#### 4. CONCEPTUAL DESIGNS

Discrete points within the range of the parametric studies were selected for more detailed consideration and conceptual design. For each of the selected concepts, the design and operational characteristics of the capsule and its systems have been specifically identified, a nominal mission profile and sequence of events determined, and conceptual design drawings prepared.

The criteria used to select these discrete points included:

- a) Near minimum weight, consistent with satisfying minimum surface science and surface lifetime requirements.
- b) A weight which provides a significant increase in surface science or lifetime capability.
- c) A weight which either satisfies the surface science and lifetime goals or is constrained by the launch vehicle shroud diameter.

Using these criteria, the capsule and system parametrics of Section 3 were used to select four discrete designs for more detailed descriptions. The science payload, mission duration, and major system selections were coordinated with NASA-Langley. A fifth design was initiated, but effort was stopped at NASA-Langley direction to concentrate the effort to the 1973 mission. The science payload selected for all four of the conceptual designs presented is identical, and is listed in Table 4-1. Two mission durations were selected: 1 day and 90 days.

Table 4-2 summarizes the more important characteristics of the five conceptual designs. The system selections were described in Section 3.3. The detailed descriptions follow in this section.

Concept I was configured to fit within a 10 ft diameter shroud, and to provide both minimum science payload and minimum surface operation duration. The major objective was to examine the characteristics of the minimum cost capsule system.

The capsule parametric studies revealed that the maximum aeroshell diameter, which would fit within the 10 ft diameter shroud, of 8.83 ft could

\* EFFORT DISCONTINUED AT NASA - LRC REQUEST TO CONCENTRATE ON CAPSULES FOR 1973 MISSION

not deliver the desired payload to the surface of Mars unless the environmental constraints were relieved. Therefore, Concept I is designed for entry into an atmosphere having a minimum density scale height of 8 km. The entry corridor was also reduced to assist in reducing the diameter required to land a given payload. A minimum entry velocity of 14 000 ft/sec was used, and the entry angle spread was taken as -15 to -18 deg. Finally, the landing system was designed to land on a maximum slope of 20 deg, and the surface winds were assumed to be 36 m/sec (118 ft/sec).

The surface payload for the assumed landed science complement was reduced by deleting the -190°F cold day environmental criterion.

All of these changes combined to allow design of a capsule which would perform the desired mission and which would fit within a 10 ft diameter shroud.

The Concept II design performs the same mission as Concept I except over the entire entry corridor and Mars environment spectrum. The diameter constraint was relieved; we used the minimum required to allow parachute deployment at Mach 2, one of the study constraints.

A significant increase in surface operational lifetime is provided in the Concept III design. The extended lifetime (to 90 days) is accompanied by changes in the lander power, communications, and thermal control systems.

Concept IV was intended to show the greatest capability within the initial study constraints - less than a 5,000 lb total flight capsule weight and fit within a 16 ft diameter shroud. After the gross definition of the concept was presented at the second oral briefing, we were directed to discontinue further effort. Section 4.4, therefore, contains only the initial definition of this concept.

The Concept V design performs the extended lifetime (to 90 days) mission under reduced environmental constraints. It retains the 30 lb landed science payload and is compatible with an 8.83 ft diameter aeroshell.

#### 4.1 Concept I

The 1226 lb Concept I capsule is designed to perform the minimum mission with acceptable risk and least cost. This consists of entry and surface atmospheric measurements, post-landed imaging and soil composition measurements with relay transmission of ten million bits of data during a one day surface lifetime. Reduction, from nominal, of environmental constraint severity and of mission flexibility has been assumed as the basis for this conceptual design. The aeroshell diameter of 8.83 ft is compatible with the 10 ft diameter booster shroud.

The capsule mission includes a boost and Earth orbit phase, an interplanetary phase, and a Mars orbit phase. The capsule then separates from the orbiter, performs a deorbit maneuver, descends and enters the atmosphere. Trajectory parameters for a typical mission are presented in Table 4.1-1. A parachute and a three engine throttleable monopropellant propulsion system provide the final deceleration. After landing, the thermal environment is maintained by a combination of isotope heaters, a heat sink, and insulation.

Prior to deorbit of the capsule, all critical systems are sequentially activated for test under the control of the central computer and sequencer (CC&S). A first level systems test will be performed which is comparable to those which can be performed after the insertion of the capsule into the sterilization canister. These tests begin several hours before the actual separation sequence and include checkout of such systems as the landing and altimeter radars, the guidance system, the telecommunications, and the propulsion system. Data obtained during this test is transmitted from the capsule by means of the capsule relay transmission system to the orbiter data system for a subsequent transmission to the Earth. These tests and separation of the forward portion of the sterilization canister are performed in sufficient time to allow analysis of the results by ground operations personnel and transmission of corrective commands or memory updating information to the capsule before deorbit. These tests culminate in the full activation of all capsule systems immediately in-

volved in the deorbit and descent operations and include the alignment of the capsule inertial reference unit.

The capsule is released pyrotechnically from the orbiter. The capsule attitude control jets provide sufficient impulse to achieve the desired physical separation between the capsule and orbiter prior to deorbit ignition. During this period, the capsule inertial reference unit is commanded by the computer to rotate to the correct attitude for the deorbit maneuver. During this phase, attitude control limits of 0.25 degrees are maintained. Transmission of engineering data from the capsule during this and subsequent phases is achieved by means of relay transmission to the orbiter at a rate of approximately 4000 bits per second.

After achieving the correct separation from the orbiter and the proper attitude for the deorbit maneuver, ignition is commanded by the sequencer. The velocity increment is measured by the longitudinal accelerometer in the guidance and control system, and the deorbit motor shutdown is initiated by the guidance computer when the required velocity is attained. A backup command for motor shutdown is provided by the sequencer at the end of a preset time interval. The magnitude and direction of the deorbit maneuver is chosen to provide the desired entry flight path angle and to insure that at the time of entry, the orbiter lags the capsule by 5° true anomaly.

Immediately after the deorbit maneuver, the capsule guidance system initiates a maneuver to place the capsule in the proper inertial attitude for the entry phase. After this is accomplished, attitude control is operated in a 3° deadband limit mode. The gyros continue to operate in an attitude hold mode. The capsule holds this attitude throughout the subsequent 3 to 10 hour descent period. Relay transmission of engineering parameters associated with the capsule environment and guidance equipment continues to be transmitted.

At an altitude of approximately 800 000 feet (preprogrammed time initiation) the sequencer activates critical capsule entry systems. This includes activation of the radar altimeter, entry science instruments, and a change in

the capsule telemetry data format for entry. At the point of sensible atmospheric contact, .05g longitudinal deceleration, the control transfers to a rate damping mode in the pitch and yaw axes to insure stability during entry. The roll axis control continues to operate in an attitude hold mode to insure proper orientation of the radar altimeter antenna.

Shortly after entry, ionization blackout may interfere with relay communications for a period as long as 150 seconds. To insure the full recovery of data obtained during this period, a core data storage buffer is used to delay all engineering and science data by an amount equal to this expected blackout duration. In this manner, data is transmitted both in real time and delayed time to insure full recovery of all data. The radar altimeter will normally begin data acquisition at an altitude of approximately 200 000 ft. The marking signal from the radar altimeter will initiate parachute deployment at an altitude of approximately 23 000 feet. The attitude control system is deactivated at this point. The aeroshell is released from the lander shortly after parachute deployment and allowed to fall clear of the vehicle. At this point the landing radar system is enabled; radar acquisition may occur, but its continuous operation is not required prior to parachute release. The parachute descent phase is chosen to be sufficiently long to insure that near terminal velocity is achieved by the parachute and to insure surface impact of the aeroshell prior to the time that landing radar operation is required.

During this period the guidance and control system is operated in a soft caging mode. This provides a best estimate of the true flight path direction and averages the effect of natural or gust induced parachute oscillations. The terminal descent engines are ignited to stabilize the vehicle and the parachute is then released on the basis of the marking signal from the radar altimeter at an altitude of approximately 6500 feet. The guidance and control system then commands the vehicle to the previously determined nominal flight path direction to provide a favorable orientation for landing radar acquisition.

After landing radar acquisition occurs, the vehicle is oriented to align the longitudinal axis with the velocity vector as determined by the landing radar. During this phase primary attitude control information is derived

from the radar while the inertial reference unit provides attitude rate damping to the system. The vehicle holds this attitude and the engines are throttled to provide the constant .8g acceleration as measured by the longitudinal accelerometer in the guidance system.

The vehicle continues in this mode until intercept of a velocity-altitude control line which is stored in the guidance computer. At this point the engines are throttled to provide the required acceleration to keep the vehicle on this flight profile. Control information in this phase is based on landing radar measured slant range and total velocity. It is used to compute attitude and acceleration commands to the engines. Actual vehicle acceleration is measured by the longitudinal accelerometer. Throughout this phase, the vehicle maintains an attitude which places the total velocity vector coincident with the roll axis. The vehicle continues down this flight path to a point of approximately 50 ft altitude at a velocity of 10 ft per sec. At this point the inertial attitude hold control is initiated and a constant 10 ft per sec descent phase, as measured by the radar, is begun. At an altitude of approximately 10 ft engine thrusting is terminated and the vehicle descends to the surface.

Immediately after landing, the surface payload is activated to begin a transmission of surface science data to the orbiter. The entry trajectory is selected so that the orbiter is approximately overhead at the time of landing. This condition provides approximately 4 minutes of useful communication time from the lander to the orbiter before loss of visibility occurs. This time is sufficient to permit transmission of  $6.4 \times 10^6$  bits of data including four wide angle images from the low resolution facsimile camera, together with initial measurements of surface meteorological conditions. This data transmission occurs at a rate of 41 600 bits per sec.

After completion of this transmission the sequencer terminates transmitter operation and the payload systems begin normal data acquisition operations. This includes deployment of the alpha spectrometer for a calibration measurement cycle. The meteorological measurements of temperature, pressure, humidity and wind are made every 15 minutes. This data is then stored in a core memory for later transmission. After the alpha spectrometer has completed its calibration

measurement, this data is transferred to core storage. The alpha spectrometer is then lowered to the surface to allow it to make surface composition measurement. The cycle of meteorological measurements continues for one full day with data being accumulated in the core storage.

The next data transmission period is initiated and terminated by sequencer command and occurs at the overflight of the orbiter near its periapse point, approximately 24.6 hours after landing. However, the uncertainty in the time of orbiter visibility is greater than the 4 minutes required for data readout. Therefore all stored data, as well as facsimile data, is transmitted completely every 4 minutes for approximately 20 minutes. This insures acquisition of one complete set of data ( $10^7$  bits) by the orbiter during its overflight. During this transmission interval, the facsimile camera is operated continuously and its data is interleaved with data from the core memory. Data read from the core memory is restored in the memory to allow repetitive transmission of the same data. Data transmitted to the orbiter is stored on a tape recorder mounted in the orbiter for later direct transmission to Earth. Following the completion of this transmission interval the normal mission of the lander is completed. However, the cycle of data acquisition and transmission is continued until battery capacity is exhausted.

The probability of mission success depends on the reliability of the equipment to perform in the design environments and the capsule's invulnerability to off-nominal conditions which may be encountered. The Concept I design does not include redundant components. This design approach was selected to facilitate concept comparison and to ultimately assure the most efficient approach to provide a high reliability capsule. In using a similar approach for the VOYAGER Capsule Phase B design (see NAS CR 89672), it was determined that a gross weight increase of 73 lbs for redundant components increased reliability for performing all functions to .71. A .71 reliability for the Concept I capsule could be achieved by adding redundant components which would increase the capsule weight about 38 lbs. This increased capsule weight is compatible with the aeroshell's 8.83 ft diameter; a maximum deployment Mach number of 1.68 would result.

The Concept I capsule, because it is designed to survive a less-than-nominal environment severity, is somewhat vulnerable to environment uncertainty. The achievement of surface operation is critically dependent upon surface temperature and on terrain slope characteristics. The achievement of entry and landing is strongly influenced by the atmospheric pressure and density, scale height, and low altitude winds. Concept I is based on the temperature environment of the "cyclic day" instead of a "cold day", 20° instead of 34° slopes, density scale height of no less than 8 km, and low altitude winds of 118 ft/sec instead of 220 ft/sec.

If the "cold day" should unexpectedly be encountered, the thermal control system would be inadequate and only the immediate post-landed relay transmission could be accomplished. Entry atmospheric measurements, a brief period of surface atmospheric measurements, and facsimile images could be obtained. The soil composition measurements would not be available. This would be termed only a partial success.

If surface slopes greater than 20° are encountered, there is a possibility but no assurance, of full success. The probability of vehicle survival would depend on the combination of slope, slope orientation, and impact velocity vector. Similarly, winds and atmospheric density distribution affect the probability of successful deceleration but determination of this probability requires consideration of the entry trajectory parameters in combination with the environment parameters. A good chance of survival exists even if design conditions are violated, since much of the design for the capsule has been based on simultaneous occurrence of worst conditions.

4.1.1 SYSTEM CONFIGURATION - The flight capsule consists of three major components:

- o Capsule
- o Sterilization Canister
- o Adapter

The capsule, after separating from the orbiting flight spacecraft delivers the entry science into the Martian atmosphere and the lander to the surface of Mars. The interior arrangement of the capsule is shown in Figure 4.1.1-1; it includes equipment for:

- o Deorbit
- o Attitude Control
- o Entry
- o Descent
- o Landing

The Sterilization Canister encloses the capsule and protects it against recontamination from terminal sterilization until separation in Martian orbit.

The adapter supports the Capsule and Sterilization Canister for all ground handling, launch, and flight loads.

A general arrangement of the flight capsule is shown in Figure 4.1.1-2 and its relationship to the launch vehicle shroud (10 ft. diameter) is shown in Figure 4.1.1-3.

The four basic structural modules that make up the flight capsule are the sterilization canister, adapter, aeroshell, and lander. (See Figure 4.1.1-4). These four structural modules, plus installed support systems, make up the total flight capsule.

4.1.1.1 Sterilization canister. - The canister consists of two structures, each nearly hemispherical in shape. Each structure is of aluminum semi-monocoque construction, stiffened by rings and external stringers. The forward and aft canisters are joined at the major diameter plane by a contained explosive separation device. This device, which is redundant, is sandwiched between the bolt flanges on the forward and aft canisters. A half-inch blanket of multilayer

4.1.1-6

FIGURE 4.1.1-4

insulation is installed on the external surface of both canister sections, with a joint at the canister separation plane.

Equipment installed in the canister, in addition to the release separation device, includes:

- o Pressurizing and Venting
- o Electrical Power
- o Inflight Checkout Programmer
- o Command Decoder
- o Telemetry/Instrumentation

The pressurizing and venting subsystem consists of redundant vent valves that vent the canister during ascent and are closed by redundant differential pressure switches; redundant evacuation valves to vent the canister during sterilization and during space flight; and two relief valves. Biological filters are installed in each valve to prevent recontamination through an open valve.

The structure of the canister assembly protects the capsule from recontamination after leaving the sterilization chamber. It completely encloses the capsule to form a sealed wall against microbial contamination.

4.1.1.2 Adapter - The adapter is made up of 16 tubular aluminum truss members, welded in a continuous ring. Members alternately converge in a zig-zag pattern at eight attach points on the capsule bus and at eight attach points on the aft canister. The adapter is attached to the capsule by eight explosive bolts.

The adapter supports the capsule for all ground handling, launch, and flight loads. The adapter is designed to install the capsule within the canister without access doors in the aeroshell or in the canister.

The only equipment mounted on the adapter is an image antenna and stub antenna. These are used to check out the capsule subsystems.

4.1.1.3 Aeroshell - The aeroshell is a single-faced, longitudinally corrugated titanium structure with closed triangular rings. The nose structure contains an instrument head which collects gas samples and measures pressure

and temperature. The remainder of the nose cap is covered externally with a non-ablative material (See Figure 4.1.1-5).

The conic segment of the aeroshell and the upper ring are covered externally with an ablating material. This material is a foamed reinforced methyl phenyl silicone, filled into honeycomb, and hard bonded to the structure.

The supports for mounting the lander in the aeroshell are installed on a structural ring. Eight bipods are attached to this ring at their base and to the lander structure at their apex. Attachment at the ring includes torsion springs to rotate the bipods outward upon lander release. Attachment at the lander is by explosive bolts at four points and compression preloaded sockets at four other points.

The reaction control system is installed in the aeroshell. It is a cold gas pressurized system, consisting of eight thrusters, four for roll control, and four for pitch and yaw control. The thrusters are mounted on the base ring at four places 90° apart. Regulators, valves, filters, tank, etc. are located in the nose area below the lander. The subsystem operation begins with the separation of the capsule from the orbiter. Firing commands to the subsystem provide attitude control during orientation, coast, deorbit motor firing and atmospheric entry. During entry into the Mars atmosphere attitude rate damping is provided.

4.1.1.4 Lander - The lander is composed of three structural elements: the footpad, the shock attenuating ring, and the base platform. (See Figure 4.1.1-6).

The footpad is made of titanium skin, radial beams, and rings. Cutouts in the lower surface allow for firing the terminal descent engines. Three stabilizing legs are mounted flush in the footpad and are spring actuated and mechanically locked to stabilize the system after landing. The landing radar antenna assembly is attached to the lower surface and is crushed on impact.

The impact attenuator is a cylinder of crushable aluminum honeycomb, such as "Trussgrid"; it is sandwiched between the footpad and base platform and crushes on impact. Eight pulley assemblies, equally spaced around the periphery,

# AEROSHELL GENERAL ARRANGEMENT CONCEPT I

4.1.1-9

FIGURE 4.1.1-5

## LANDING SYSTEM

tie the footpad and base platform together, preventing separation during landing impact and forcing total attenuator loading.

The base platform is made up of eight equally spaced radial titanium I-beams and is the mounting base for the surface payload, and the capsule support equipment (See Figure 4.1.1-7).

The three terminal descent engines are mounted on the base platform, with the nozzles flush with the footpad. The nozzles are frangible and will be crushed during landing. Terminal propulsion system tankage is mounted on the base platform.

The combined deorbit motor and parachute support structure is attached to the top of the base platform.

The support structure consists of four aluminum tubes that attach at the upper end to a machined ring. This ring supports the deorbit motor, which is attached by three bolts to facilitate thrust alignment. The base attach points of the four primary support tubes consist of one explosive bolt and one shear pin each.

Below the deorbit motor attach ring is another structural ring. The parachute canister mounts on the lander centerline, and attaches to the lower ring. The catapult loads are reacted by the base platform through bearing of the parachute catapult barrel.

There is an explosive bolt separation joint just above the lower ring at each of the four tubes. Separation force is supplied by energy stored in compression springs at each bolt. These bolts are activated to separate the deorbit motor and the upper portion of the support structure. The remaining portion of the structure, which supports the parachute installation, is separated by activating explosive bolts at the base of each tube.

The parachute riser assembly is attached to the base of the four tubes above the mounting plane. The lower support structure, parachute canister and the thermal curtain are removed by differential drag when the parachute is released.

# LANDER GENERAL ARRANGEMENT CONCEPT I

4.1.2 MAJOR SYSTEMS - The flight hardware elements of the major systems of the capsule are discussed in this section in the following order: science (both entry and landed), communication, power, guidance and control, sequencer, thermal control, propulsion, auxiliary aerodynamic decelerator aeroshell, landing system, canister and adapter.

4.1.2.1 Science. - The science subsystems are identical for the two design concepts which have a single diurnal cycle lifetime, Concept I and Concept II. The same instruments are also used for the two concepts using the 90 day mission lifetime, Concept III and Concept V. However, the operating sequence is changed for the long duration missions.

Requirements and Constraints - The performance requirements in Figure 4.1.2.1-1 were obtained from the LRC Mars Missions Objectives Document while the constraints were obtained from the point design. For example the 24 watts is the electrical power required for the surface science instruments and does not represent an upper limit on electrical power that can be made available if it is justified. The performance requirements are discussed in detail in Section 3.2.1.

Figure 4.1.2.1-2 shows a total data rate constraint of less than 350 bits per second for the entry science subsystems. Higher data rates can be made available, however, by reducing the amount of systems monitoring data during entry, since the total entry data transmission capability is over 1 300 bits per second.

Physical Description - The landed science and entry science instruments are listed in Figure 4.1.2.1-3. Presently available instruments which are in an advanced state of development were selected, in order to achieve minimum program cost. The values for the mass spectrometer in the landed science list are in parentheses since this instrument was not included as part of the selected concept. (The mass spectrometer measurements were not listed as part of the science requirements.) However, as discussed in Section 3.2.1, it may be possible to use the mass spectrometer both for entry measurements and measurements on the surface. By operating the mass spectrometer for one minute once every 6 hours, the amount of electrical energy required is so small that the use of the mass spectrometer on the surface has only a slight effect on the lander

FIGURE 4.1.2.1-3

design. The science equipment total weight is 53 lb.

Most of the science instruments are located on the outside portion of the lander rather than in the thermally insulated equipment compartment, as shown in Figure 4.1.2.1-4. Some of the science equipment, such as the alpha spectrometer electronics and the pressure sensor, is located inside the equipment compartment. This greatly reduces the temperature requirements on this equipment and makes it possible, in the case of the pressure sensor, to use a presently available unit at a large savings in cost. This will also be the case for the mass spectrometer if it is located on the lander and used for surface measurements.

Operational Description - The operational sequence, as shown in Figure 4.1.2.1-5, provides for making all the science measurements listed in the performance requirements for a one day mission. The atmospheric measurements can be made once every fifteen minutes. The instruments are turned on, and after approximately a one minute warm-up the pressure, temperature, and humidity are determined. The only problem associated with the meteorology sequence was the wind measurements. The wind varies greatly in a period of only a few seconds. Therefore, it is desirable to leave the wind instrument on continuously, and to determine the average wind, the time when the wind is below the threshold of the instrument, the peak wind, and the instantaneous wind at the end of the fifteen minute period. Only this data is then transmitted, thus keeping the wind data to a reasonable value of 3 920 bits per day as compared with 9 408 bits per day for the total atmospheric data.

The next problem in selecting the sequence is associated with the alpha spectrometer. It is desired to make a background measurement during a period of three to five hours, a standard sample measurement during another period of three to five hours, and a surface measurement during a period of approximately 20 hours, without operating the alpha spectrometer at night. Since the required counting time is too long for a single day mission, it was assumed that electrical heaters and thermal insulation would be added to the alpha spectrometer in order to operate it at night. The electrical power subsystem can provide 4.5 watts for heater power to the alpha spectrometer which is sufficient to maintain the entire head at a high enough temperature for nighttime operation. However, if the sensor head packaging is redesigned so that only a fraction

## VIEWING AND DEPLOYMENT CAPABILITY

# MINIMUM LIFETIME SCIENCE MEASUREMENT SEQUENCE

4.1.2-7

FIGURE 4.1.2.1-5

of the head is insulated and heated during the nighttime operation, then the required heater power will be less than 4.5 watts. This will significantly reduce the energy and weight requirement for the power supply subsystem.

The next problem in selecting the measurement sequence is associated with the facsimile camera. Since data storage is not available for more than  $2 \times 10^5$  bits, the camera must generate data at an average rate which is equal to the transmission rate capability of the communications system. Immediately following landing, a ten minute period is available for relay transmission from the lander. In the worst case, however, only two minutes of the data transmitted will be received and relayed to earth. Therefore, only 30 seconds is available for each of the four wide angle frames generated by the wide angle camera.

The use of a scan period as short as 30 seconds will make the noise equivalent radiance  $5 \times 10^{-5}$  watts/(cm<sup>2</sup> steradian) for a 0.4 inch lens. For the high resolution facsimile camera which is operated at the end of the day, the noise equivalent radiance for the 30 second scan period will be approximately  $10^{-4}$  watts/(cm<sup>2</sup> steradian) for a one-inch lens. The 16.7 line per second rate required for scanning the high resolution field in 30 seconds is higher than the normal design limit of 5 to 10 lines per second. A special scan technique or design will thus be required for this camera. For both the wide angle and the high resolution cameras, it is desirable to scan horizontally for the high rate line scan. This simplifies the focus control since the rate at which the focus is varied is greatly reduced.

Since a command link is not presently included in the selected concepts, it will be necessary to program the focus control based on an expected distance to the surface. A few simple on-board techniques are available for controlling the focus of the high resolution camera. For example, the distance that the alpha spectrometer must be lowered before it reaches the surface can be used to determine the distance from the camera to the ground adjacent to the alpha spectrometer. This distance can then be used to control the focus of the camera for frames near the alpha spectrometer.

Development Status - It is anticipated that no severe problems will be encountered in developing these instruments to withstand the sterilization procedure. The development status of the instruments varies greatly. The

pressure sensor, for example, is almost an off-the-shelf item. On the other hand, the high resolution facsimile camera has been designed and prototypes have been fabricated for a few of the components but not for the entire camera. The alpha spectrometer will have to be modified in order to obtain either a higher counting rate (so that the surface measurement can be made using only the daylight hours) or thermal control for operation at night. Even with the nighttime operation, a stronger source will be required than the one which is presently used on the lunar alpha spectrometer in order to compensate for the decrease in source strength during the transit from Earth to Mars.

4.1.2.2 Communications system functional description. - The function of the communications equipment is to collect the scientific and engineering data, format the data sources into a coherent data stream, temporarily store the information, and transmit the data at the appropriate times. Table 4.1.2.2-1 lists the capsule data requirements.

The functional description is divided into two parts; the capsule-mounted communications equipment which weighs 53.3 lb and the orbiter-mounted communications support equipment weighing 37.4 lb.

4.1.2.2.1 Capsule mounted communications equipment: The capsule mounted communications equipment contains the following subsystems:

- a) Entry antenna
- b) Entry radio
- c) Entry telemetry
- d) Entry instrumentation
- e) Relay antenna
- f) Relay radio
- g) Landed storage
- h) Landed telemetry
- i) Landed instrumentation

Figure 4.1.2.2-1 is a block diagram of the equipment, and Table 4.1.2.2-2 is a list of the salient characteristics of the design. Table 4.1.2.2-3 is a list of the physical parameters of the equipment.

System Description - The equipment has four operating modes in addition to the inflight checkout and memory dump modes. These modes are:

- a) Deorbit descent
- b) Atmospheric entry
- c) Terminal descent
- d) UHF relay

o Deorbit Mode - The deorbit descent mode is used from separation to the initiation of atmospheric entry. The 210 data channels are formatted by the combined entry telemetry commutator and landed telemetry commutator into an

interlaced tube format at a 440 bps rate. This bitstream is subbit encoded to 3960 bps and transmitted to the spacecraft by the 3 watt noncoherent frequency shift keyed (FSK) entry transmitter. Subbit encoding is used here to keep a constant 3960 bps transmission rate thereby avoiding mode switching in the spacecraft bit synchronizer. Delay storage is not required during descent.

- o Atmospheric Entry Mode - The atmospheric entry mode begins at 800 000 feet and continues until the initiation of terminal descent. During atmospheric entry 278 data channels are formatted by the combined entry and landed telemetry commutators into an interlaced tube format at 1320 bps. This bitstream is transmitted in real time and also transmitted twice in delayed time to insure that the data gathered during the plasma "blackout" is reliably transmitted to the orbiter at least one time. The core storage unit in this mode is programmed as a tapped delay line. The length of the line is 120 seconds, and the tap is at 60 seconds. The real time plus the two delayed time bitstreams are combined into a 3960 bps stream, and transmitted to the orbiter over the entry UHF transmitter.

- o Terminal Descent Mode - The terminal descent mode begins when the landing radar comes on and lasts until landing. The system operation during terminal descent is the same as that in atmospheric entry except that a different set of data is collected.

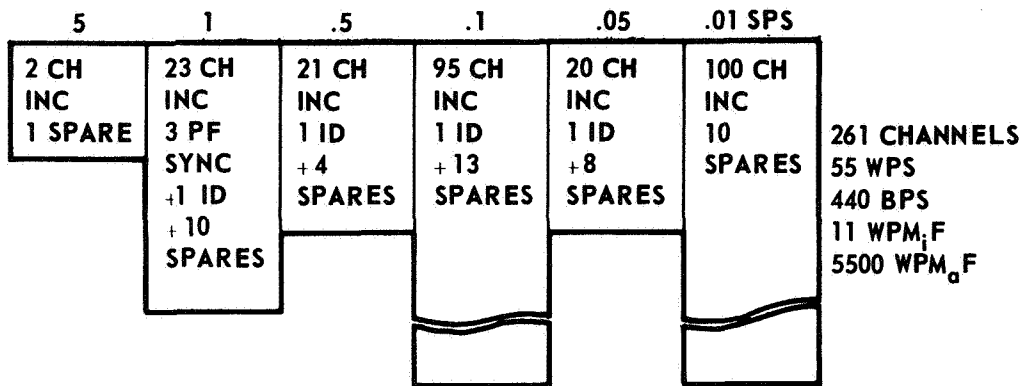

The data formats for the preceding three modes are shown in Figure 4.1.2.2-2.

The entry transmitter power level was selected on the basis of the maximum power required in entry at a 5 deg central angle between the capsule and the orbiter at the time of entry. From Figure 3.2.2-7, for the worst case atmosphere, trajectory, and surface roughness, this is 25.4 dBm. This power requirement is not exceeded when parachute oscillations less than 30 deg occur in any atmosphere. Since the 25.4 dBm computation was made on a 2560 bps rate, 1.9 dB is added to account for the 3960 bps rate, bringing the required level to 27.3 dBm. In addition, 6.4 dB must be added for a 120 deg orbiter antenna over a 55 deg antenna. A 3 watt transmitter thus has a 1.1 dB excess margin. Referring to Table 3.2.2-2, this power level is equivalent to a 5060 Km design range for the no multipath condition. Table 4.1.2.2-4 defines the link characteristics.

2) TRANSMITTING ANTENNA GAIN, SPACE LOSS AND  $E/N_0$  CORRESPOND TO THE WORST CASE COMBINATION OF THE TRAJECTORIES INVESTIGATED.

o Landed Relay Mode - The UHF relay mode consists of transmitting the stored diurnal cycle data plus real time imaging during periapse passage.

The scientific and engineering data is collected at a sample rate of once each 15 minutes and stored in the core. This data is interleaved with the imaging data, taken during the orbiter overflight, and relayed via a 400 MHz link. The worst case landing dispersion due to atmospheric and entry uncertainties is  $\pm 4.7$  deg, i.e., a maximum spacecraft lead of 2.4 deg for a VM-9, -15 deg entry, and a maximum spacecraft lag of 7 deg for a VM-8, -15 deg entry (for a consistent 5 deg control angle at entry). From Figure 3.2.2-26 the minimal transmitter output power to transmit  $10^7$  bits is 2.5 watts for 4 minutes, or a 41.6 Kbps rate. An additional .87 dB is required in order to use a 120 deg rather than a 90 deg orbiter antenna. Thus, the "required" power is 3.07 watts. From Figure 3.2.2-23, the maximum slope uncertainty at this rate is  $\pm 3.2$  minutes. The net result of these three factors, (atmospheric uncertainty, power/time for  $10^7$  bits, and slope uncertainty) is that 17.27 minutes of transmission time is required to assure the 4 minute  $10^7$  bit "window." With 2.13 dB excess margin, the resultant power requirement is 5 watts, which corresponds (reference Table 3.2.2-2) to a design transmission range of 1480 km with a 120 deg orbiter antenna. Table 4.1.2.2-5 defines the link characteristics.

Because of this choice of capsule-orbiter relative geometry at entry (5 deg central angle), the orbiter will lead the capsule by 2.4 deg at landing in the worst case (VM-9, -15 deg entry). Allowing for 20 seconds warmup time, and transmitting at a power level (5 watts) and bit rate (41.6 K bps) commensurate with a  $10^7$  bit transmission on the second day permits 155 seconds of transmission and return of 6.45 M bits after landing.

4.1.2.2.2 Orbiter mounted support communications equipment: The spacecraft mounted support communications equipment contains the following subsystems:

- a) UHF antenna
- b) UHF radio
- c) Storage
- d) Telemetry
- e) Command

2) TRANSMISSION NEAR PERIAPSIS FOR 4 MIN PER PASS

Figure 4.1.2.2-3 is a block diagram of the equipment, and Table 4.1.2.2-6 is a list of the physical characteristics.

The UHF antenna receives both the entry and the landed signals. It is a helix with a gain of 3.22 dB and a beamwidth of 120 degrees. The diplexer transfers the entry telemetry signal at 3960 bps to the entry receiver, and the landed telemetry signal at 41.6 kbps to the landed relay receiver.

The entry receiver is a conventional double super-heterodyne frequency shift keyed receiver with noise temperature of 555°F. The mark and space filters have a bandwidth of 10 kHz to accommodate a maximum 6 kHz Doppler, and thus operate at a bandwidth pulsewidth product of 2-1/2. The entry bit synchronizer is a standard phase lock loop, integrate and dump device which incorporates a phase gate to track the direct path phasor and lock out the indirect (multipath) phasor. The entry bit synchronizer runs at a constant 3960 bps rate, independent of the entry telemetry system mode.

The landed relay receiver is similar to the entry receiver, but with 41.6 kHz bandwidth mark and space filters, and it operates at a bandwidth pulsewidth product of unity since no appreciable Doppler will be present. The landed relay bit synchronizer is a standard phase lock loop, integrate and dump device. The special phase gate is not required for this receiver, because the landed system only transmits at high elevation angles, where multipath is not a problem. The synchronizer rate is 41.6 kbps.

Both of the receivers feed the data distribution unit, which in turn either routes the incoming data directly to the orbiter or to the orbiter mounted support tape recorder. The data distribution unit is the central interface equipment between the orbiter and the capsule (prior to separation) and the capsule support equipment.

This central data interface simplifies the capsule-orbiter interface problems. In addition to routing the entry and relay data to the orbiter, it also routes the radio commands, via the orbiter command receiver, to the support equipment command decoder, and routes the support equipment commutator

**SPACECRAFT MOUNTED  
SUPPORT COMMUNICATIONS EQUIPMENT**

**TABLE 4.1.2.2-6****SPACECRAFT MOUNTED COMMUNICATIONS EQUIPMENT**

ITEM	SIZE (CU IN.)	WEIGHT (LB)	POWER (W)
UHF ANTENNA	DIA = 9.4, L = 11.2	0.2	-
DIPLEXER	8	.8	-
UHF RECEIVERS	240	11.4	5.8
TAPE RECORDER	414	13.8	2.0
DATA DISTRIBUTION UNIT	128	3.2	2.0
SUPPORT COMMUTATOR	64	2.6	2.0
COMMAND DECODER	168.5	5.4	1.3

and the payload commutators (prior to separation) to the orbiter telemetry system.

The tape recorder serves as an intermediate storage device between the entry and landed relay transmissions and the spacecraft retransmission. At moderate bit packing densities of 1 kbp<sub>i</sub> per track, 257 feet of one inch tape are required to assure the transmission of a  $10^7$  relay picture with the net landing time and surface slope uncertainties. This recorder would accommodate a 3.03 hour deorbit/entry time. The entry time range, however, is up to 9 hours. Thus, a 764 foot tape is required. With the "nominal" 3.42 hour orbital descent time only 290 feet of tape would be required. The recorder may not be required in the support equipment area if the orbiter recorder can be made available.

The support equipment commutator serves as a remote multiplexer to the spacecraft telemetry. This commutator monitors the operation of the two UHF receivers, the bit synchronizers, the tape recorder, the data distribution unit, the command decoder, and the in-flight checkout equipment.

The spacecraft command receiver receives all the commands from Earth and routes all of the commands to the support equipment and the capsule prior to separation to the support equipment command decoder. The support equipment decoder then routes the commands to the using subsystems.

4.1.2.2.3 Development status: No special development problems are anticipated for any of the equipment in the conceptual designs. Every type of component required in the designs has been successfully flown on previous missile and spacecraft programs.

A sterilizable tape recorder, not required in the conceptual designs, would require development. Although some work has progressed on "high temperature" tapes, and various recorder components, no comprehensive "tape system" work has been undertaken. Such an effort would be principally directed toward the definition of the long term chemical effects of the potentially damaging sterilization process. A sterilizable tape recorder could probably be developed in 1-1/2 to 2 years. However, some uncertainty would remain as to its reliability after an extended life.

4.1.2.3 Power system. - The electrical power system provides the basic energy storage and power management for the lander and surface payload electrical equipment. Concept I assumptions pertinent to the power system are:

- a) One diurnal cycle mission
- b) Isotope heat for surface payload
- c) Relay link communication

4.1.2.3.1 Design requirements and goals: Trade studies have shown, in general, that a lighter weight landed system evolves when the total required energy storage is divided into two components: that for descent and entry, and that for surface operation. This weight saving occurs because the battery used for descent and entry may be allowed to freeze after touchdown, while surface operations require a battery to survive the cold, night temperatures. Hence, a thermal control weight penalty is involved which is dependent upon the mass and surface area of the battery to be protected. Generally, the added thermal control weight for a single, compact battery, sized for descent and entry plus surface operation, is greater than the weight penalty of reduced energy density for two, separate batteries: one for descent and entry, and one for surface operation.

The electrical power and energy requirements for descent and entry are shown in Figure 4.1.2.3.1-1. For a descent period of 3.5 hours, 400 watt-hours are required for equipment operation. Allowing a 6% distribution loss factor, the required battery capacity is 425 watt-hours.

The electrical power and energy requirements for the surface payload operations are graphically illustrated by the power profile of Figure 4.1.2.3.1-2. Isotope heat is provided for surface payload thermal control, but an electrical energy contingency is required, as indicated by the shaded area, to provide heat to the deployed science package (alpha spectrometer). The total energy requirement is 308 watt-hours, and allowing a 6% distribution loss factor, the required battery capacity is 330 watt-hours.

4.1.2.3.2 System description: The electrical power system consists of two sealed, manually activated, silver-zinc primary batteries, three automatically activated, silver-zinc batteries, two battery chargers, one DC-to-DC converter-regulator, and a power switching and logic unit. A block diagram of the power system is shown in Figure 4.1.2.3.2-1. The power system weight and location are as follows:

<u>ITEM</u>	<u>LOCATION</u>	<u>WEIGHT (LBS)</u>
Battery Charger (2)	Canister & Surface Payload	6.0
Auto Activated Battery (3)	Lander	15.0
Manually Activated Battery	Lander	22.0
Switching & Logic	Lander & Surface Payload	13.0
Manually Activated Battery	Surface Payload	14.0
DC/DC Converter	Surface Payload	<u>4.0</u>
Total Weight		74.0

The DC-to-DC converter accepts unregulated power from the orbiter solar array and provides regulated power to the power transfer switch in the power switching and logic unit. The power transfer switch contains the power sensing and transfer equipment associated with the transfer of the distribution bus from orbiter power to battery power when orbiter power is not available or when commanded by the sequencer. The distribution bus and associated switches provide power to the using subsystems on commands from the sequencer.

The two, sealed, manually-activated, silver-zinc primary batteries provide the main energy storage for the lander and surface payload. The descent/entry battery is designed for a high discharge rate to provide the power for descent and entry while maintaining adequate voltage regulation during the peak power demand of entry. In addition, this battery provides the power for the telemetry, instrumentation, and thermal control subsystems when orbiter power is not available during interplanetary cruise.

The surface payload battery is designed to provide the power for surface operation at a relatively low rate of discharge. This battery is sized to provide energy for one diurnal cycle of surface operations. This battery must survive the Martian night environment, and thus is located in the insulated,

# LANDER POWER SYSTEM BLOCK DIAGRAM

isotope-heated compartment of the surface payload to maintain its temperature above 50°F. That portion of the power switching and logic unit associated with surface payload operations and equipment of other subsystems producing heat during surface operations are also located in this compartment.

The descent/entry battery is maintained in a charged condition during cruise and is recharged after orbiter maneuvers by its battery charger operating from orbiter power. The surface payload battery is also maintained in a charged condition during cruise by its battery charger operating from orbiter power.

Each battery charger has two modes of operation. In the first mode it charges the battery at a constant potential of 1.98 volts/cell but with current limiting at a 20-hour rate. Charging current is sensed, and when this current reduces to the 100-hour rate, the battery is put on float charge at 1.87 volts  $\pm$  .01 volts per cell. Each time power is removed from the battery charger and then reapplied, the charger reverts to the first operating mode.

Three automatically activated silver-zinc batteries are also contained within the electrical power system. These batteries are designed to be heat sterilized in a dry charged condition. Each battery is activated using a gas generator containing dual pyrotechnic initiators. Activated stand life is at least 12 hours. The batteries are a high rate design and are used during descent and entry to supply the high pulse current requirements for the attitude control and propulsion subsystems, pyrotechnic initiators, and deployment actuators.

It is assumed that power for the lander support equipment mounted in the orbiter will be provided directly from the orbiter power system. This equipment requires a maximum of 13.1 watts.

4.1.2.3.3 Operational description: During the pre-launch phase and until about 5 minutes before lift-off, the launch complex operational support equipment provides power to the electrical power system. During the launch phase, power is supplied from the descent/entry battery for operation of the instrumentation and telemetry subsystems. Transfer to orbiter power occurs upon completion of the launch phase and after deployment of the orbiter solar array. Subsequently, and during interplanetary cruise, orbiter power is regulated by

the DC-to-DC converter and distributed to the using subsystems and battery chargers by the power switching and logic unit.

During periods of high power usage or midcourse maneuvers, orbiter power may not be available to the lander and surface payload. At this time, on command from the orbiter, and failing that upon detection of loss of orbiter power, the distribution bus is transferred to descent/entry battery power by the power switching and logic unit to maintain operation of the instrumentation and telemetry subsystems. When orbiter power becomes available again, the distribution bus is again supplied by regulated orbiter power via the DC-to-DC converter, and the descent/entry battery is again placed on float charge. The maximum amount of energy removed from the descent/entry battery during each of these periods is not expected to exceed 10 percent of its capacity.

Approximately one hour prior to separation, on command from the sequencer, the distribution bus is transferred from orbiter power to the descent/entry battery. From this time (pre-separation checkout), until landing, power is provided by the descent/entry battery.

The three automatically activated batteries are initiated, on command from the sequencer, during pre-separation checkout. Two of these batteries provide power to separate, redundant buses for pyrotechnic initiation. All three batteries are connected to a third bus for operation of high pulse current equipment.

After landing, on command from the sequencer, the distribution bus is transferred from the descent/entry battery to the surface payload battery. Surface operations continue until the surface payload battery is exhausted.

4.1.2.3.4 Performance: The performance characteristics of the power sources are tabulated in Table 4.1.2.3.4-1. Additional power system equipment is two battery changes (3 pound each), a convertor/regulator (4 pounds), and the power switching and logic unit (13 pounds). The power switching and logic unit will be subdivided into two sections: one for descent and entry equipment; one for surface payload equipment.

The performance characteristics of the manually activated batteries are predicated on the projected energy density of Figure 3.2.3-7. Therefore the

<p><b>DESCENT/ENTRY BATTERY</b> TYPE = PRIMARY; SEALED, MANUALLY ACTIVATED, SILVER-ZINC CAPACITY = 425 WATT-HOURS ENERGY DENSITY = 19 WATT-HOURS/POUND WEIGHT = 22 POUNDS WET STAND LIFE = 12 MONTHS CYCLE LIFE = 4 CHARGE/DISCHARGE CYCLES AT 100% OF CAPACITY REGULATION = <math>29.5 \pm 4.5</math> VOLTS TEMPERATURE LIMITS: WET STORAGE = 0°F TO 60°F NORMAL USE = 50°F TO 120°F</p>
<p><b>SURFACE PAYLOAD BATTERY</b> TYPE = PRIMARY; SEALED, MANUALLY ACTIVATED, SILVER-ZINC CAPACITY = 330 WATT-HOURS ENERGY DENSITY = 24 WATT-HOURS/POUND WEIGHT = 14 POUNDS WET STAND LIFE = 12 MONTHS CYCLE LIFE = 4 CHARGE/DISCHARGE CYCLES AT 100% OF CAPACITY REGULATION = <math>28 \pm 4</math> VOLTS TEMPERATURE LIMITS: WET STORAGE = 0°F TO 60°F NORMAL USE = 50°F TO 120°F</p>
<p><b>HIGH CURRENT BATTERY</b> TYPE = PRIMARY; AUTOMATICALLY-ACTIVATED, SILVER-ZINC CAPACITY = 20 WATT-HOURS ENERGY DENSITY = 4 WATT-HOURS/POUND WEIGHT = 5 POUNDS WET STAND LIFE = 12 HOURS DRY STORAGE LIFE = 24 MONTHS REGULATION = <math>27 \pm 7</math> VOLTS PEAK LOAD CURRENT = 25 AMPERES TEMPERATURE LIMITS: UNACTIVATED = -65°F TO 160°F ACTIVATED = 20°F TO 120°F</p>

performance is necessarily conservative and assumes continuing development of heat sterilizable silver-zinc batteries.

4.1.2.3.5 Development status: Except for the batteries, the electrical power system components are not long lead time development items. However, battery development is critical for a 1973 launch date. Maximum development effort is required in order to obtain adequate engineering data on wet life, cycle life, and loss rates for heat sterilizable batteries. Little data exists on wet life and cycle life of heat sterilizable systems. Data is urgently needed on the cycle life capability after the extended wet stand period of interplanetary cruise in order to determine the battery capacity and depth of discharge that will provide the cycle life required for specific missions. Since the interplanetary cruise period is about 220 days, and a 90-day surface mission capability is desirable, at least a year or more of testing will be required before significant data is obtained. Therefore, immediate initiation of such a program is imperative to design a vehicle for the 1973 launch date.

An alternate solution to wet heat sterilization of sealed, Ag-Zn batteries is sterile activation of a dry, heat-sterilized battery and electrolyte and subsequent sterile insertion or assembly into the flight capsule. This technique has been proven feasible with no failure of the sterilization procedure. Furthermore, long wet life, silver-zinc batteries of current, non-sterile technology were tested, indicating that little development may be required to extend current technology to a sterile battery by the dry heat sterilization technique.

4.1.2.4 Guidance and control. - The guidance and control system consists of attitude/deorbit velocity control electronics (inertial measurement unit, and central computer and sequencer), landing radar, and radar altimeter.

4.1.2.4.1 Attitude/deorbit velocity control electronics: This system consists of an Inertial Measurement Unit (IMU) and Central Computer and Sequencer (CC&S) with their power supplies. The IMU senses inertial body rates about all three body axes and acceleration along the roll axis. The CC&S accepts and processes the IMU signals and landing radar range and velocity measurements and generates commands for the propulsion subsystems to guide and control the capsule from orbiter separation to touchdown on the Martian surface. The CC&S also performs all capsule and lander sequencing. The design selection of the control sensors, computer, and flight sequencing has been derived from parametric studies presented in Sections 3.2.4 and 3.2.5. The weight savings resulting from this design approach is discussed in detail in Section 3.2.5. The guidance and control equipment total weight is 37 lb.

Control Requirements and Design Goals - Table 4.1.2.4-1 summarizes the control system operations during each mission phase. Table 4.1.2.4-2 shows the control accuracy design goals and calculated system performance. The system performance in all cases meets or exceeds the requirements and design goals.

The 300 meter separation required between the orbiter and the capsule before deorbit motor ignition is accomplished within 20 minutes, to limit the system attitude drift before this critical event. The requirement for system checkout capability after enclosure in the sterilization canister is provided both on the pad and during flight.

System Description - A functional block diagram of the attitude/deorbit velocity control electronics is shown in Figure 4.1.2.4-1, and a summary of characteristics is given in Table 4.1.2.4-3. The strapped-down IMU with a digital computation capability provides a minimum weight and risk system and also the greatest mission accuracy and flexibility.

The IMU contains three rate integrating gyros, one integrating accelerometer, and a power supply. This unit is mounted on the lander, near the capsule center of mass, such that the accelerometer senses decelerations along the roll

axis and the gyros sense rotations about each orthogonal body axis. A single accelerometer, mounted on the roll axis, is adequate to meet the deorbit velocity accuracy requirement. Each IMU sensor uses the ternary (pulse-on-demand) rebalance principle. This technique provides lower biases while also allowing higher dynamic ranges. Each pulse from a gyro or the accelerometer represents, respectively, a precise incremental attitude or velocity change.

The CC&S is a general purpose digital computer with a central processor, core memory, control circuitry, and gating and interface circuitry. A power conditioner, with special guard against memory loss, is self-contained. This package is mounted on the lander, next to the IMU. A memory sizing study showed a need for 1850 permanent storage data words and program instructions and 426 variable data words. A 4096 word capacity (of which 512 are updatable) is provided for mission growth. This capacity also provides for all pre-separation checkout testing and landing flight sequencing. The data word of 20 bits is based on simulation studies which show 19 bits are adequate to limit round off errors in the linearized Euler dynamic equations used for attitude stabilization. The other bit is provided for arithmetic sign. The operational speed and serial arithmetic was selected after establishing the maximum iteration speeds for the attitude control and flight sequencing subroutines.

Operational Description - The operational sequence is shown in Figure 4.1.2.4-1. Approximately 24 hours prior to capsule/orbiter separation, the CC&S is activated. All systems and built-in test equipment are exercised according to the CC&S stored memory sequence. The first test function verifies the CC&S memory content, and checks specific test algorithms. The IMU sensors are monitored while operating to detect unacceptable gyro drifts, accelerometer bias, and scale factor instability. The system is also checked end-to-end (i.e., from the gyro response to the propulsion element driver signal).

One hour prior to separation, the IMU is activated under the control of the CC&S incorporated landing flight sequencing program. The separation attitude reference is initialized in the CC&S. After separation, the control system maintains a three axis attitude hold ( $+0.25$  deg) using body attitude error summed with body rate in commanding the Reaction Control System (RCS)

operation. The computer calculated rate stabilizes the attitude control by providing damping.

During the coast-to-deorbit phase, the capsule is maneuvered to the de-orbit thrust attitude. This control mode is identical to the preceding, except that the reference frame is rotated, one axis at a time, at a constant 1.0 deg/sec rate. The vehicle axes follow the rotated reference frame. After maneuver termination, the system returns to the +0.25 degree, three axis attitude hold mode for deorbit thrusting. Thrusting is terminated using the integrated axial accelerometer output.

After deorbit thrusting, the capsule is maneuvered into a zero entry angle of attack attitude. This maneuver mode is identical to that used for the de-orbit thrust maneuver. During the period between maneuver completion and entry, computer calculated attitude stabilization is employed. A three axis attitude hold deadband of  $\pm 3$  degrees results in minimal limit cycle fuel consumption and control accuracy degradation. The computer accumulates IMU attitude change pulses, calculates inertial body rates, and generates RCS jet commands from error signals derived from linearized Euler angle dynamic equations. These attitude calculations eliminate any "coning" errors resulting from limit cycle motions. The low iteration speeds of the subroutine during this phase allow the computer logic to be cycled on/off. This logic idle technique reduces the computer power consumption by 53%.

At atmospheric entry (0.05g) attitude control is switched to pitch and yaw rate damping ( $\pm 3$  deg/sec rate limiting). The roll attitude hold ( $\pm 3.0$  deg) is continued. Rate damping in the pitch and yaw axes assists in maintaining aerodynamic trim, and provides a stable environment for the entry experiments. The preferred roll mode allows the use of a fan beam radar altimeter with significant accuracy, range, and weight improvements relative to an altimeter system with a hemispherical radiation pattern.

Calculation of the aerodynamic velocity vector direction begins at atmospheric entry. During entry at peak dynamic pressure, the capsule roll axis is closely aligned to the velocity vector. At this time a computer routine is initiated, and the computer begins the calculation of the direction cosines

of the body axes. The routine effectively filters the computed pitch and yaw Euler angles, and uses them to rotate the reference frame. In this manner the computed roll axis reference follows the gravity turn without following the higher frequency body oscillations caused by winds and other disturbances. The angles derived from these computed direction cosines become the initial pitch and yaw Euler angles used at the start of terminal descent. This technique provides a favorable attitude for landing radar acquisition.

A radar altimeter mark initiates the parachute deployment/aeroshell separation sequence. During parachute descent no reactive control is employed. The calculation of the aerodynamic velocity vector direction is continued. Terminal descent engine ignition and parachute release is initiated by a signal from the radar altimeter.

At the beginning of terminal descent an inertial attitude hold mode is established, using the computed pitch and yaw Euler angles from the velocity vector direction routine. In the attitude hold mode, attitude error and body rate are summed to form proportional throttle commands. A constant axial acceleration command with an acceleration feedback loop closed through the IMU is used.

After landing radar acquisition, the attitude control is switched from inertial attitude hold to radar steering in the pitch and yaw body axes to null the radar measured lateral velocity components. Upon intercepting the pre-programmed descent profile, the command of the axial component of the terminal propulsion thrusters is generated according to the pre-programmed range/velocity function. At a pre-set slant range (e.g., 50 ft), attitude control is switched back to inertial hold, and a constant velocity (e.g., 5 ft/sec) is commanded until engine cutoff at 10 ft altitude.

Performance - System performance is presented in Table 4.1.2.4-2 along with design goals. In addition to all dynamic error sources, the attitude accuracy error analyses have also included all irreducible initial system errors. These include: (1) IMU-to-capsule mounting alignment uncertainty, (2) capsule-to-orbiter mounting alignment uncertainty, and (3) orbiter deadband limit cycle motions at capsule separation. The calculated capsule control performance meets or excels all requirements and design goals.

Development Status - The digital IMU will incorporate sterilizable sensors. The selected gyro has been developed under a special sterilization design/development contract. The accelerometer has been built, tested, and successfully operated in temperature environments which are as stringent as those imposed by sterilization. Neither type of sensor poses ETO test cycle problems, since they are both hermetically sealed. The concept of body mounted, pulse rebalanced sensors has been successfully used for the PRIME system mission, which has environmental extremes exceeding those expected for this capsule. The LM abort sensor assembly (IMU) containing pulsed rebalanced gyros and accelerometers has successfully completed qualification testing.

The computer can be mechanized from existing components and technology. Similar magnetic core systems have been test proven to withstand the sterilization environment. The magnetic core memory technology has been space qualified in numerous previous applications.

4.1.2.4.2 Landing radar system: The landing radar system employs three CW (continuous wave) velocity sensing beams and a single linear FM/CW (frequency modulation/continuous wave) range sensing beam. This design is based on a minimum modification to the LM (Lunar Module) landing radar. Landing radar derived range and velocity information is provided from parachute separation altitude to engine cut-off. Parametric study results of the landing radar system are discussed in Section 3.2.4.2.

Requirements and Constraints - The primary requirements of the landing radar are as follows:

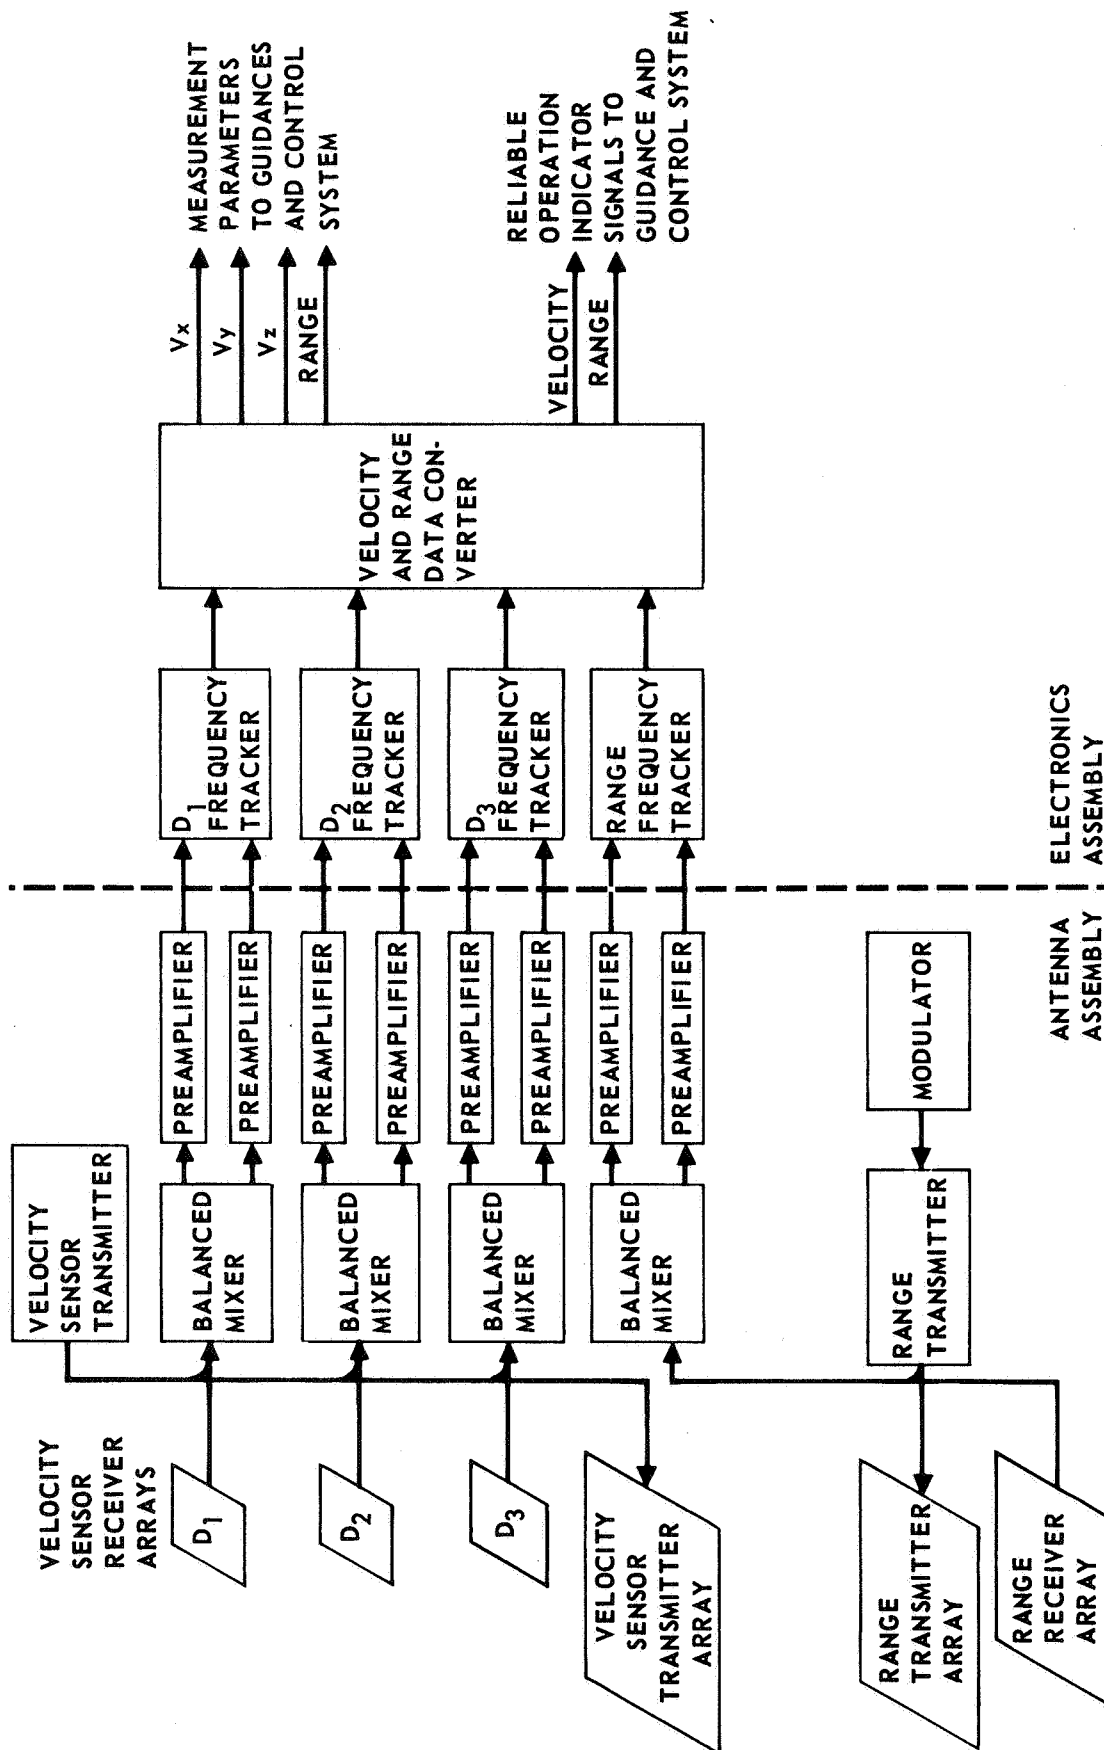

- a) To provide continuous roll axis slant range and 3-axis velocity vector measurement from parachute separation to engine cut-off (6500 to 10 ft.).
- b) To provide terminal phase measurement errors ( $3\sigma$ ) of less than  $\pm 1.4\%$   $\pm 5$  ft. for slant range and  $\pm 1.5\%$   $\pm 1.5$  fps for the resolved velocity components.
- c) To provide capability for checkout of the radar after canister enclosure and during flight.

System Description - A block diagram of the landing radar is shown in Figure 4.1.2.4-2, and a summary of characteristics is given in Table 4.1.2.4-4. This landing radar is based on a minimum modification to the existing LM landing radar. This radar employs three CW velocity sensing beams and a single sawtooth FM/CW range beam. The velocity beams are positioned at half cone angles of 25 degrees from the roll axis and at clock angles of 0, 110, and 180 degrees. The range beam is positioned along the lander roll axis between the 0 and 180 degree velocity beams. Two solid state transmitters are used, one each for the velocity and ranging functions. A single integrated planar array antenna contains interlaced velocity and range transmit arrays together with the four receive arrays.

Each of the four receive channels employs quadrature homodyne detection to facilitate sense determination and discrimination against double sideband spurious signals. After pre-amplification, the beat frequencies are supplied to frequency trackers. The tracker output frequencies are proportional to the doppler or range frequencies (plus a constant offset) on each beam. The velocity tracker signals are resolved into orthogonal components, converted to serial binary form, and supplied to the guidance and control system. Reliable lock and operation signals are generated to indicate individual tracker, as well as range and velocity sensing, operational status. A CRO (Conditional Reliable Operation, see Section 3.2.4.2) mode is available if near zero doppler situations are encountered. The electronics assembly provides for self-testing by generation and injection of test signals into the preamplifiers.

Physical Description - The 38.6 lb landing radar system is divided into the antenna assembly and electronics assembly. The antenna assembly consists of a single interlaced transmitter array, four receiver arrays, velocity and range transmitters, mixer crystal assemblies, and audio frequency amplifiers. The 20 x 24.6 x 6.5 inch antenna assembly is located on the underside near the center of the lander footpad, resulting in a clear field of view. The electronics assembly contains the four frequency trackers, data converters, power supply, and cabling subassembly. Size, weight, and power requirements for the two assemblies are given in Table 4.1.2.4-4. In addition, approximately two pounds

of microwave absorbing material are placed on the aeroshell nose cap interior to allow radar testing after canister enclosure.

Operational Description - Prior to deorbit the landing radar is energized for self-testing. To assure adequate varactor frequency multiplier warm-up time, the radar is again energized at 100 000 ft based on a radar altimeter mark. The radar search/track function is inhibited until after separation from the aeroshell.

After aeroshell separation and during the parachute descent phase, the radar is allowed to acquire and track the surface signals to verify proper radar operation. Landing radar measured data is not used for external control during parachute descent because the possible extreme attitudes and attitude rates prevent continuous tracking. (In the event that a radar malfunction is detected during parachute descent, the parachute may be retained to touchdown.)

At an altitude of about 6500 ft the parachute is released via a radar altimeter mark. By this time the aeroshell has reached the surface. At about the same time the descent engines are ignited, an inertial attitude hold mode is initiated, and the radar search/track mode is updated causing the trackers to search over pre-determined frequency intervals corresponding to the conditions at 6500 ft. Within two seconds after engine ignition, the inertial attitude hold mode has established favorable attitude and attitude rate conditions for radar acquisition.

Range and velocity track is normally established within 5 seconds after engine ignition. The resolved orthogonal velocity components and the slant range measurement are supplied to the central computer and sequencer. The lander is then caused to align with the measured velocity vector. During this maneuver attitude rate limiting is employed to avoid excessive range and velocity frequency tracking rates.

The radar derived range and velocity information is used continuously during the remaining portion of the terminal descent, until engine shutdown at 10 ft altitude. During this latter portion of flight, landing radar mode switching will be performed (based on a prescribed combination of measured

range and velocity) wherein tracker bandwidths are reduced and the range beam frequency deviation is increased to provide increased accuracy.

Performance - The performance characteristics of the landing radar are summarized in Table 4.1.2.4-4. These characteristics are determined by the radar beam configuration, the per beam transmitting and receiving parameters, and signal processing techniques. The terminal phase accuracies of Table 4.1.2.4-4 are based on computer studies described in Reference 4.1.2.4-1. Accuracy will be degraded during the initial phase of radar operation due to less favorable altitude, attitude, and attitude rate conditions.

Development Status - The landing radar system design is predicated on the maximum utilization of the existing LM radar system. The major modifications required to adapt it to the Mars mission are as follows:

- a) Alternate Antenna System - The antenna beam configuration must be changed to locate the ranging beam at the beam group centerline. An engineering model of an antenna providing this beam configuration has been fabricated and tested.
- b) Protection from Plume Damage - The heat load from the descent engines will require antenna thermal design modifications. The present slotted waveguide array technique will require RF transparent material, either bonded to the array faces or filled in individual slots, to prevent exhaust gas backflow damage.
- c) Sterilization - Design modification to incorporate sterilizable components and materials is required. From Reference 4.1.2.4-1 it is estimated that 5.3% of the present LM part population is questionable with regard to sterilization.

Additional required modifications include the provision for in-flight monitoring and check-out, power supply redesign for the lander input voltage levels, tracker parameter optimization for the Martian descent conditions, and incorporation of the Conditional Reliable Operation mode.

4.1.2.4.3 Radar altimeter system: A non-coherent pulse radar altimeter system similar to system III of Section 3.2.4.3 is described herein. This

system differs from the baseline system III because of the inclusion of a secondary antenna to allow operation after aeroshell separation.

Requirements and Constraints - Radar altimeter system requirements and constraints are summarized in Section 3.2.4.3. Factors of particular significance to this system are listed below.

- a) It provides continuous altitude information from an altitude of 200 000 ft to lander release from the parachute for entry science data correlation.
- b) It provides discrete altitude marks for event sequencing, including landing radar turn-on, parachute deployment, parachute release, and engine ignition.
- c) It provides altitude accuracy consistent with the constraints of Section 3.2.4.3.
- d) It provides the capability for radar checkout after canister enclosure and during flight.

System Description - The 18.5 lb radar altimeter is a non-coherent pulse system employing leading edge tracking. A triode cavity transmitter operating at 1.0 GHz provides 5  $\mu$ sec pulses with a 500 w peak power. A low noise figure super-heterodyne receiver with RF amplification is used. Two separate antennas are used. The primary antenna is a single T-fed slot mounted on the aeroshell, which provides fan beam coverage during entry with the capsule held in a preferred roll position. The secondary antenna is a linearly polarized crossed slot configuration mounted on the lander and used after separation from the aeroshell. The system provides altitude information from 200 000 ft to the point of parachute release. A block diagram of the radar altimeter is shown in Figure 4.1.2.4-3 and the system characteristics are summarized in Table 4.1.2.4-5.

Referring to Figure 4.1.2.4-3, the 5  $\mu$ sec, 500 w transmitter pulses are generated by the high voltage power supply and modulator pulsing the triode oscillator grid. The modulator trigger pulse train is derived from the timing circuit. The RF energy is transmitted through the duplexer and RF switch to

either the primary antenna, secondary antenna, or dummy load. (The dummy load is used for checkout after canister enclosure.) A diode gate isolates the receiver during the transmit period. The return signal is amplified at RF, converted to IF, amplified at IF with AGC, envelope detected, shaped to accentuate the leading edge, and then applied to the tracking section. The tracker positions the range gate on the detected video pulse. Elapsed time measurement (transmit-to-receive) yields the altitude estimate. Acquisition is performed by programming the range gate position from maximum to minimum delay.

During the descent and entry phase the capsule is held in a preferred roll position, permitting a single T-fed slot antenna to be used. This single slot provides 90 degree roll x 160 degree pitch coverage. After aeroshell separation and during parachute descent a single crossed slot antenna (with in-phase feeding to yield linear polarization) is used to provide 120 x 120 degree coverage about the roll axis.

Physical Description - The radar altimeter system consists of the electronics assembly, primary antenna, and secondary antenna.

The electronics package size, weight and primary power requirements are 400 cu in., 13.3 lbs., and 28 w, respectively. The electronics assembly contains the RF parts section (antenna switch, isolator, circulator, and dummy load), the receiver section (diode switch, RF amplifier, local oscillators and mixer), the IF section (IF amplifier with AGC circuitry, envelope detector and pulse shaping network), the transmitter section (triode cavity oscillator, modulator, and high voltage power supply), the tracking and timing sections (integrated circuits and discrete parts), and the main power supply. The electronics assembly is located on the lander.

The primary antenna (single T-fed slot) is 7 x 2 x 2 in., and is mounted on the aeroshell behind an RF window. The slot is located at the preferred roll position with the seven inch dimension perpendicular to the capsule roll axis. The antenna weight is estimated to be 2.2 lb, exclusive of the window and mounting structure. The secondary antenna (cavity backed, crossed slot), is located on the lower surface of the lander. The estimated size and weight requirements are 7 x 7 x 2 in. and 3 lb, respectively.

Operational Description - Prior to deorbit, after the sterilization canister has been released, the radar altimeter is energized for self-testing. After deorbit, the altimeter is again energized and begins transmitting via the primary antenna before an altitude of 600 000 ft is reached. Acquisition normally occurs prior to 200 000 ft altitude. At 100 000 ft a marking signal is generated to apply primary power to the landing radar. At a pre-set altitude, a marking signal is supplied to initiate parachute deployment and aeroshell release.

One second prior to aeroshell release, the sequencing function provides a "modulator holdoff/antenna select" signal, which disables the transmitter during aeroshell release and antenna switching. Four to six seconds after separation, the altimeter begins transmitting via the secondary antenna, reacquires the surface, and establishes the altitude track. To discriminate against near returns from the aeroshell, 5 microsecond receiver blanking is used. At a pre-set altitude, a marking signal is generated to initiate parachute release and terminal propulsion engine ignition. Altimeter operation is terminated after landing radar acquisition.

Performance - The performance characteristics are summarized in Table 4.1.2.4-5. The basis for the accuracy estimate is given in Section 3.2.4.3. The primary error contributors are the fluctuating error due to surface roughness and the surface state altitude bias error. The indicated single sweep detection probability of 0.95 (corresponding to a +3db per pulse S/N at 210 000 ft) results in a cumulative detection probability of greater than 0.9985 at 198 000 ft altitude.

Development Status - The radar altimeter system is based on existing pulse altimetry techniques. No long lead time or state-of-the-art items are required to design and fabricate this system. Design areas requiring particular attention are:

- a) Electrical Breakdown - The basic design must minimize potential breakdown problems. Anti-breakdown insulation materials should be investigated and tested to achieve reliable protection at minimum weight for the temperature and pressure extremes expected.

- b) Sterilization - The altimeter design must incorporate sterilizable components and materials. Component, subassembly and complete system testing will be required.

4.1.2.5 Sequencer system. - The sequencer system elements provide the means for accomplishing, independent of Earth command, the time-based events for:

- a) Equipment checkout prior to capsule separation and mission commitment
- b) Control of the separation, deorbit, entry, and landing systems
- c) Control of the surface mission equipment for a mission duration of one to three days

The memory technique and the hardware integration approach selected for these functions are discussed in Section 3.2.5.

4.1.2.5.1 Design requirements: The primary sequencer system design requirements and goals are:

- a) To provide precise time lapse countdown from an externally originating start signal or a mission "mark".
- b) To provide a system design that has minimum size, weight, and power requirements.
- c) To provide reference frequencies to other using subsystems.
- d) To provide alterable memory for mission updates.
- e) To provide built-in self-test capability after enclosure in the sterilization canister.

The first design requirement results from a need for precise circuit closure timing, sometimes referenced from a mission "mark" with unpredictable time occurrence (i.e., sensing 0.05 g at atmospheric entry, passage of 23 000 ft altitude, etc.). This capability requires a special unit interface design approach and internal program technique. The units associated with event sequencing for each mission phase above meet these design requirements and goals.

4.1.2.5.2 System description: A functional block diagram of the 6.7 lb sequencer system is shown in Figure 4.1.2.5-1, and a summary of characteristics is given in Table 4.1.2.5-1. The integration of all pre-landing sequencing into the computer, which must be available for guidance and control computation purposes

**\*THIS EQUIPMENT WEIGHT IS CHARGED TO THE GUIDANCE & CONTROL SYSTEM**

provides a minimum hardware weight and the most simple interface design concept (See Section 3.2.5). The separate unit to control surface operations minimizes power consumption and thermoregulation requirements for clock stability.

The central computer and sequencer (CC&S) is a general purpose digital computer with a central processor, core memory, control circuitry, and input/output section (See Section 3.2.4). The memory unit employs a data word of 20 bits and has a capacity of 4096 words (512 of which are updatable). Only 11% of the stored data, 10% of the operational power, and 28% of the size and weight of the CC&S are attributable to the checkout testing and flight sequencing functions.

During checkout testing, the decoder/driver decodes all CC&S test commands, and selects an existing surface sequencer and timer (SS&T) output driver when possible. This technique eliminates duplication of approximately 50% of the SS&T normal mission output drivers to perform the checkout function.

The first motion switch is an electromechanical switch that verifies orbiter/capsule separation and signals the CC&S to continue the landing flight sequence. Without receipt of this signal, the CC&S inhibits all further sequencing, to prevent ignition of the capsule deorbit motor while it is still attached to the orbiter.

The sequencer and timer for surface operations control (SS&T) is a core memory device with two major program control branches. One executive control routine provides all the one time only and other asynchronous event timing planned during the equipment erection and UHF relay transmission periods. During the night an experiment sequence of 2 minutes on followed by 13 minutes off for the same instrument and data storage equipment is repeated. A special repeat cycle timer mode allows shutoff of the main memory, reducing power consumption by 75%.

The impact sensor is an acceleration sensing device on the lander which senses surface touchdown and starts the SS&T for controlling the landed mission. A backup starting command is provided by the CC&S.

Both the CC&S and SS&T have a built-in self-test capability to permit system test after enclosure in the sterilization canister. The units have

"fast time" and "safe time" design features, to allow running through sequence portions faster than real time without actuating mission equipment (i.e., pyrotechnics). Both units have an update capability until capsule separation from the orbiter.

4.1.2.5.3 Operation description: Approximately 24 hours prior to capsule/orbiter separation, the CC&S activates and controls all systems and built-in test equipment (to simulate mission inputs where practical) according to the stored memory sequence. The system responses to the test commands are telemetered to earth for mission readiness evaluation. Earth commands for a test sequence recall or CC&S and SS&T memory update are made as directed by test data.

At 1 hour prior to separation, the orbiter commands the CC&S to start a separation sequence countdown. The CC&S controls the equipment start-up required and issues the separation command. The first motion switch detects the actual physical separation and notifies the CC&S to initiate the first post-separation countdown sequence.

The post-separation to surface touchdown period consists of five sequence groups. At each consecutive mission "mark" the last sequence group data is ignored and the new sequence group time-word interrogations are started. For example, at the radar altimeter "mark" of 23 000 ft, all prior sequence words are branched around in the computer program and the aerodecelerator deployment phase words are called into the program.

The SS&T is started by the impact switch at touchdown. Its equipment control actions and timeline are fixed by the memory data provided prior to separation. No command capability exists to modify its program after separation.

4.1.2.5.4 Performance: The timing accuracies indicated in Table 4.1.2.5-1 exceed all mission requirements and impose no stringent clock specifications. The time-word resolutions are chosen on mission requirements. The 50 msec time quantization of the CC&S is provided in order to time the de-orbit and entry attitude maneuver command signals accurately.

4.1.2.5.5 Development status: Both the CC&S and SS&T can be mechanized from existing components and technology. Similar magnetic core systems have been test proven to withstand the sterilization environment. The magnetic core

memory technology has been space qualified in numerous previous applications.

4.1.2.6 Thermal control. - The thermal control system maintains capsule and lander temperatures within their allowable ranges throughout all mission phases. During flight the lander is provided with a controlled temperature environment by the provisions for capsule thermal control. When exposed to the Martian surface environments the lander operates independently from the separated aeroshell. The primary results of the point design study are definition of thermal control requirements, establishment of configurations, and generation of sizing and performance data.

4.1.2.6.1 Requirements and constraints: Because the environments, requirements and constraints of the flight phase and the landed phase are appreciably different, they will be discussed separately.

Flight Phase - Equipment located within the lander is limited to a temperature range of 20 to 70°F. Several components located outside the lander, such as propulsion equipment, require active temperature control as the capsule cools during its flight away from the sun toward Mars. Electrical heaters will be required, using power drawn from the solar panels on the orbiter. The amount of power needed depends on the solar distance, and the performance of multilayer insulation provided on the forward portion of the sterilization canister. The isotope heaters used for post-landing thermal control will also reduce flight phase electrical heating requirements. The canister must be retained during Mars orbit to avoid losing the insulation.

The capsule environment changes during orbital descent as the capsule becomes directly exposed to the combined solar/deep space environment. An important consideration during this period is to avoid overcooling the ablative heat shield. During the Voyager Phase B study a minimum design temperature of -150°F was selected, to avoid possible low temperature degradation. However, preliminary testing of McDonnell ablator material has demonstrated integrity to -300°F.

Landed Phase - The major requirement of the thermal control design is to provide sufficient heat retention by insulation and internal heating to prevent overcooling equipment during nighttime while concurrently

avoiding overheating during Mars daytime operations. The temperature limits of operating equipment are divided into two parts: 1) equipment requiring 0 to 100°F, and 2) equipment requiring 50 to 125°F. These ranges apply to equipment installed inside the lander. Other experimental equipment located outside the lander will experience the full range of Mars surface ambient conditions, and these must be individually temperature controlled.

The equipment power profile consists of a continuous power level of 9.0 watts, with peaks to 54 watts during relay transmission periods. The post landing environment consists of a nominal cyclic day temperature environment, with day and night extremes of 120 and -150°F respectively, for both ground and atmosphere. A sand and dust environment that will degrade thermal control coatings has been assumed. Winds, which affect lander heating and cooling, have also been assumed. Additional details on the Mars surface environment, plus those of the flight phases, are presented in Section 3.2.6.

4.1.2.6.2 System description: Major elements of the thermal control system are insulation blankets and panels, electrical and radioisotope heaters, and heat sink material. In addition, a thermal curtain is provided over the base of the aeroshell to retain heat during orbital descent, deflect propellant reaction products, and reduce base heating to aeroshell mounted equipment. Optical coatings (paints or tapes) will be used on surfaces that require specific optical properties.

Flight Phase Equipment - The major thermal control components for the flight phase have been defined for a flight orientation in which the capsule is partially shaded by the solar panels on the orbiter.

o Multilayer Insulation Blanket - The multilayer insulation blanket is located on the outside of the forward portion of the sterilization canister. It provides the primary thermal resistance between the capsule and the deep space environment. The blanket consists of layers of plastic film with a highly reflective coating on each layer. As such, it acts as a series of radiation heat transfer barriers. This is the most

efficient type of insulation for covering large surface areas in a vacuum environment.

o Electrical Resistance Heaters and Thermostat Control Devices - Heat must be generated within the capsule to replace that which is lost to space if an acceptable equilibrium temperature level is to be maintained. The heat will be generated with electrical resistance heaters powered by solar panels on the orbiter. These heaters will be placed on components that require a higher minimum temperature than the average environment. Thermostat control devices will be used with heaters that have a capacity greater than 3 watts, to conserve power and avoid overheating.

o Insulation Packages for Individual Components - The components that are provided with heaters will also be insulated to minimize the heat loss and conserve heater power. The proposed insulation is a fiberglass type that can be efficiently fabricated to fit the individual components. Insulation of individual components is also necessary to preclude excessive cooldown during periods when power from the orbiter is not available for heaters (e.g., during trajectory corrections).

o Thermal Curtain - The thermal curtain is required to protect components and structure within the aeroshell from aerodynamic heating during atmospheric entry. It also prevents damage to the lander thermal coatings during deorbit motor firing and reduces heat loss from the rear of the aeroshell during orbital descent.

o Thermal Control Coatings - Preparation of the surface of most aeroshell mounted equipment and structure is necessary to distribute the internal heat properly. The most critical surface is the exterior of the aft portion of the sterilization canister. The optical properties, solar absorptance and infrared emittance, of this surface determine the overall temperature levels of the capsule and their change as the solar distance increases from Earth to Mars.

Landed Phase Equipment - The thermal control equipment on the lander must be sufficient to maintain equipment temperature limits and also be compatible with the flight phase environments.

- o Insulation - Thermal insulation that completely surrounds the lander is provided to protect equipment from the low Martian nighttime temperatures. This insulation along with internal heat generation provides a temperature range of 0 to 100°F for lander equipment. Within this volume a smaller insulated compartment is provided which maintains the battery, transmitter, and sequencer from 50° to 125°F. This arrangement results in less total insulation weight than would be required if all equipment were maintained between 50° and 125°F.

- o Isotope Heaters - Heat lost through the insulation is replaced by isotope heaters. These are completely passive and operate throughout the mission by radioactive decay of isotope material, probably promethium 147 or plutonium 238.

- o Heat Sink Materials - Metallic heat sinks are provided to increase the thermal inertia of the lander. This approach effectively dampens the temperature variations of the lander in the cyclical external environment. Heat sink material absorbs heat by virtue of its high specific heat value.

- o Thermal Control Coatings - The external surfaces of the lander are subject to the combined solar heating and Martian surface environment. Thermal coatings are required that have low solar absorptance and are sand and dust resistant, to avoid excessive thermal performance degradation. The thermal analysis was performed assuming that the coatings were degraded to values experienced in McDonnell tests, i.e., with solar absorptance of 0.5 and emittance of 0.9.

4.1.2.6.3 Physical description: The selected thermal control design is defined in terms of flight phase and landed phase weights. The sum of these weights is the total thermal control weight allocation for the mission. These weights were based on the parametric studies described in Section 3.2.6.

Flight Phase Equipment - The selected flight phase configuration results in use of the thermal control components described below:

#### Flight Phase Thermal Control Components

<u>Component</u>	<u>Weight(lb)</u>	<u>Description</u>
Canister-Mounted Equipment	19.0	Multilayer insulation blanket (1/2 in thick), thermal coatings
Aeroshell-Mounted Equipment	3.0	Equipment insulation, thermal coatings, heaters
Thermal Curtain	-	Silica Cloth (See Section 4.1.2.9)
Lander-Mounted Equipment	25.0	Equipment and tankage insulation, heaters
Total	<u>47.01b</u>	

Landed Equipment - The selected Martian Soft Lander is shown schematically in Figure 4.1.2.6-1. Included in this sketch are the various thermal control devices located within the two compartment lander design. A weight breakdown for the thermal control system is given below.

#### Lander Thermal Control Components

<u>Component</u>	<u>Weight (lb)</u>	<u>Description</u>
Outer insulation	21.8	3" thick, 4 lb/ft <sup>3</sup>
Isotopes in outer compartment	1.5	7.5 watts
Heat sink material in outer compartment	1.4	beryllium
Battery compartment insulation	1.3	0.4" thick, 4 lb/ft <sup>3</sup>
Isotopes in battery compartment	4.4	22 watts
Heat sink material in battery compartment	7.4	beryllium
Total	<u>37.8 lb</u>	

4.1.2.6.4 Operational description: The thermal control system operates throughout the mission to maintain equipment and structural temperatures through the utilization of constant power level isotope heaters, and thermostatically controlled electrical heaters during the flight phase. Isotope power requirements are reduced by use of thermal coatings and insulation.

## THERMAL CONTROL SCHEMATIC – DUAL COMPARTMENT LANDER

### CONCEPT I

- EXTERNAL ENVIRONMENT –  
ONE CYCLIC DAY, (–150 TO + 120°F)

Flight Phase - In the vicinity of Earth, solar heating of the capsule is sufficient to alleviate the necessity of using heaters. However, as the solar distance gradually increases, the capsule cools until temperatures reach the thermostat control points. Thereafter, the electrical heaters maintain the capsule at the controlled temperatures.

The sterilization canister is retained throughout the Mars orbit period to avoid excessive cooling of equipment and increased heater power.

After separation, and during orbital descent, the thermal inertia of the equipment, the resistance to heat loss by the insulation, and the supply of internally generated heat results in the avoidance of need for heater power.

Landed Phase - The post-landing thermal control system is capable of maintaining both lander compartments above their minimum operating temperatures during one cyclic day. Isotopes and heat sinks are provided to both compartments in sufficient quantity to avoid excessive cooling of the compartments during the night and avoiding overheating of the compartments during daytime operation.

During the daytime a portion of the heating energy provided by the isotope heaters and by the equipment power profiles is stored within the compartments. The relatively large thermal inertia of the equipment, structure, battery, and heat sinks prevents appreciable temperature rise.

Similarly, this same thermal inertia prevents excessive temperature drop during the nighttime operation. A portion of the heat loss to the environment is replenished by the isotope heaters and the equipment power profiles to the two compartments.

4.1.2.6.5 Performance characteristics: The lander thermal performance is characterized by the temperature variation of the two compartments for the cyclic day environment anticipated. During the daytime the maximum battery and equipment compartment temperatures attained are 90°F and 80°F, respectively; at night these temperatures drop to the lower operating limits of 50°F and 0°F, respectively.

4.1.2.6.6 Development status: The major thermal control development problem is the lander insulation. Its performance in the Martian surface environment after exposure to the mission environments of sterilization, launch vibration, long term vacuum, entry, and landing has not been evaluated. Particularly uncertain is the effect of insulation installation and attachment techniques on overall thermal performance.

Long term space exposure effects on the aft canister thermal coating are a potential problem. If the degradation characterized by increased solar absorptance is neither too rapid nor too large, the absorptance is beneficial to capsule thermal control since temperatures will not decrease as much during the flight from Earth to Mars.

A second thermal coating problem occurs after landing when the lander exterior coatings are exposed to the Martian sand and dust environment. Preliminary McDonnell tests have indicated that solar absorptance can increase by a factor of two or more after exposure, and that extended exposure can result in complete removal of the coating material. Several coating materials, specifically flame sprayed aluminum oxide, white pigmented silicone elastomer and white porcelain enamel, have demonstrated resistance to the environment with respect to both retention of optical properties and erosion resistance.

4.1.2.7 Propulsion. - The propulsion functions required by the Mars capsule are accomplished with three separate systems: a solid propellant rocket motor for deorbit, a cold gas system for attitude control, and a throttleable, monopropellant system for terminal deceleration. The description, usage, and development status of these systems are discussed in this section.

#### 4.1.2.7.1 Deorbit Propulsion System:

System Description - The deorbit propulsion system is a spherical, solid propellant rocket motor, containing provision for thrust termination prior to propellant burnout. The motor configuration is shown in Figure 4.1.2.7-1 and is functionally described in Figure 4.1.2.7-2. The motor consists of a titanium case; an igniter assembly (consisting of an igniter and a safe-and-arm device); a partially submerged, high expansion ratio nozzle; and an internal-perforated, case bonded propellant grain. The propellant is a saturated, hydroxy-terminated polybutadiene/aluminum/ammonium perchlorate formulation providing good thermal stability and adequate physical properties at the required sterilization temperature.

A thrust termination mechanism holds the nozzle to the motorcase. The mechanism consists of a split clamp ring and a pyrotechnically-actuated retention bolt.

The physical and performance characteristics of the rocket motor are presented in Figure 4.1.2.7-3.

Operational Description - Arming of the deorbit igniter is effected by a signal from the timer and sequencer 55 minutes before capsule-orbiter separation. Upon receipt of this signal, an electro-mechanical actuator on the igniter safe-and-arm (S&A) physically aligns the pyrotechnic initiators with the igniter. A position transducer on the S&A verifies that the igniter is armed. Approximately 5 seconds prior to deorbit rocket ignition, the ignition system is enabled by a command from the capsule timer and sequencer. At the command to ignite the deorbit motor, the pyrotechnic initiators ignite the pellets in the igniter which in turn ignite the igniter sustainer charge. The igniter sustainer exhausts into the motor propellant cavity, providing sufficient heat and pressure to ignite the main propellant charge.

DEORBIT MOTOR

Simultaneous to the command to ignite the motor, the timer and sequencer arms the pyrotechnic retention bolt on the thrust termination mechanism. Thrust termination of the deorbit motor is achieved by releasing the nozzle. By activating the contained explosive bolt, the thrust termination ring that attaches the nozzle to the motorcase is released. The sudden pressure decrease associated with releasing the nozzle terminates propellant burning. Thrust termination can be initiated at any time after ignition. A thrust spike will occur at thrust termination; however, the duration of the spike is extremely short ( $\sim 20$  ms). This technique of thrust termination has been used successfully in the Jupiter and Titan II vernier rocket motor applications.

o Development Status - The deorbit motor as depicted in Figure 4.1.2.7-1 is a conventional configuration, containing no design features which have not been flight-proven in previous space applications. The design is very similar to the Titan II vernier, Gemini retro, and Surveyor retro rockets. Nevertheless, a major development effort is required to meet the sterilization requirements. Sterilization feasibility has not been adequately demonstrated on a solid propellant motor of applicable size. Current off-the-shelf propellants, liners, and insulations have exhibited serious degradation when exposed to the sterilization environment. New propellant systems containing saturated binders and stabilized oxidizer appear very promising based on tests of small samples. However, the only motor of significant size to be loaded with a saturated propellant and subjected to the sterilization environment was a 50 lb<sub>m</sub> Syncom motor, tested by JPL. The motor survived one heat cycle without noticeable adverse effects but failed in the subsequent heat cycle due to propellant-steel incompatibility. (The motorcase was unlined.) Considering the failure mode, it is significant that the motor survived the first heat cycle in good condition.

Sterilizable, high performance motor designs are believed to be achievable with these latest propellant developments, but more development work must be done, particularly on insulation materials. Plasticizers and dehydrated fillers in the insulation can degrade the bond between the propellant and insulation. Many of the methods employed to enhance the stability and physical properties of the propellant at high temperature are suitable, as well, for insulation materials. This must be accomplished, however, without serious degradation to the insulation properties.

Other available component materials such as O-rings, nozzles, and igniters appear to be adequate.

#### 4.1.2.7.2 Attitude Control System:

System Description - Attitude control of the capsule is provided by a cold gas propulsion system utilizing gaseous nitrogen as the expellant. The functions performed by the system are:

- a) separation of the capsule from the orbiter, and
- b) attitude control and rate damping of the capsule during deorbit, descent, and atmospheric entry.

The attitude control system is presented schematically in Figure 4.1.2.7-4 and is functionally described in Figure 4.1.2.7-5. Gaseous nitrogen is stored at high pressure in a spherical pressurant tank. The nitrogen is isolated from the remainder of the system by a pyrotechnic-operated valve. Upon system activation, the isolation valve is actuated allowing the gas to flow from the storage tank to the regulator where the pressure is reduced to design operating pressure. The gas emerging from the regulator is then distributed to the eight thrust chamber assemblies installed about the periphery of the aeroshell. The regulator and thrust chamber assemblies are protected from contamination by in-line filters. Test ports are provided to allow for pre-flight testing of the system components. System condition prior to activation and during operation is monitored by temperature and pressure instrumentation. The performance and physical characteristics of the attitude control system are presented in Figure 4.1.2.7-6.

Operational Description - The attitude control system is loaded with gaseous nitrogen and sealed before terminal sterilization. Approximately 5 seconds prior to separation of the capsule from the orbiter, the attitude control system is activated by actuating the pyrotechnic isolation valve at the outlet of the nitrogen storage tank. Electrical signals to the eight TCA solenoid valves permit nitrogen flow and thrust. Four TCA's provide pitch and yaw control while the remaining four provide roll control.

The separation of the capsule from the sterilization canister is performed by firing the four pitch and yaw TCA's simultaneously to provide a separation

velocity increment of 1.5 feet per second. Attitude control during this maneuver is affected by utilizing reverse guidance logic, wherein the thruster(s) producing a control moment in the direction of the disturbance is momentarily shut-down. Orbit attitude control, attitude stabilization during deorbit motor firing, descent attitude control, and attitude rate damping during Mars atmospheric entry is obtained by pulsing the TCA's in response to guidance and control commands. Approximately 4 seconds after full deployment of the parachute, the aeroshell, including the attitude control system, is jettisoned.

Development Status - Extensive development of cold gas nitrogen propulsion systems has been performed. The Ranger, Mariner, Surveyor, and Lunar Orbiter vehicles have used cold gas nitrogen systems. From these and other programs, hardware adaptable to Mars capsule requirements are available. Additional effort will be required to meet the mission requirements and to develop compatibility with the sterilization environment. Sterilization of a cold gas propulsion system will affect the design of the storage tank, regulator and valves.

#### 4.1.2.7.3 Terminal Propulsion System:

System Description - The terminal propulsion system is a gas-pressurized, monopropellant hydrazine system containing three variable-thrust engines. A schematic of the system is shown in Figure 4.1.2.7-7 and is functionally described in Figure 4.1.2.7-8.

System pressurization is accomplished with high pressure helium gas which is stored in a spherical 6Al-4V titanium tank. The helium pressurant is isolated before use by a normally-closed pyrotechnic valve installed immediately downstream of the pressurant tank. A manual access valve provides a means of pressurant servicing, a regulator is provided to maintain constant propellant feed pressure. The regulator is isolated from propellant vapors during the long Earth-Mars transit time by normally-closed pyrotechnic valves. Relief valves are employed to provide system protection in the event of an over-pressure situation. Burst diaphragms separate the relief valves from the pressurant system to prevent relief valve leakage at normal operating pressure.

# SCHEMATIC DIAGRAM OF TERMINAL PROPULSION SYSTEM

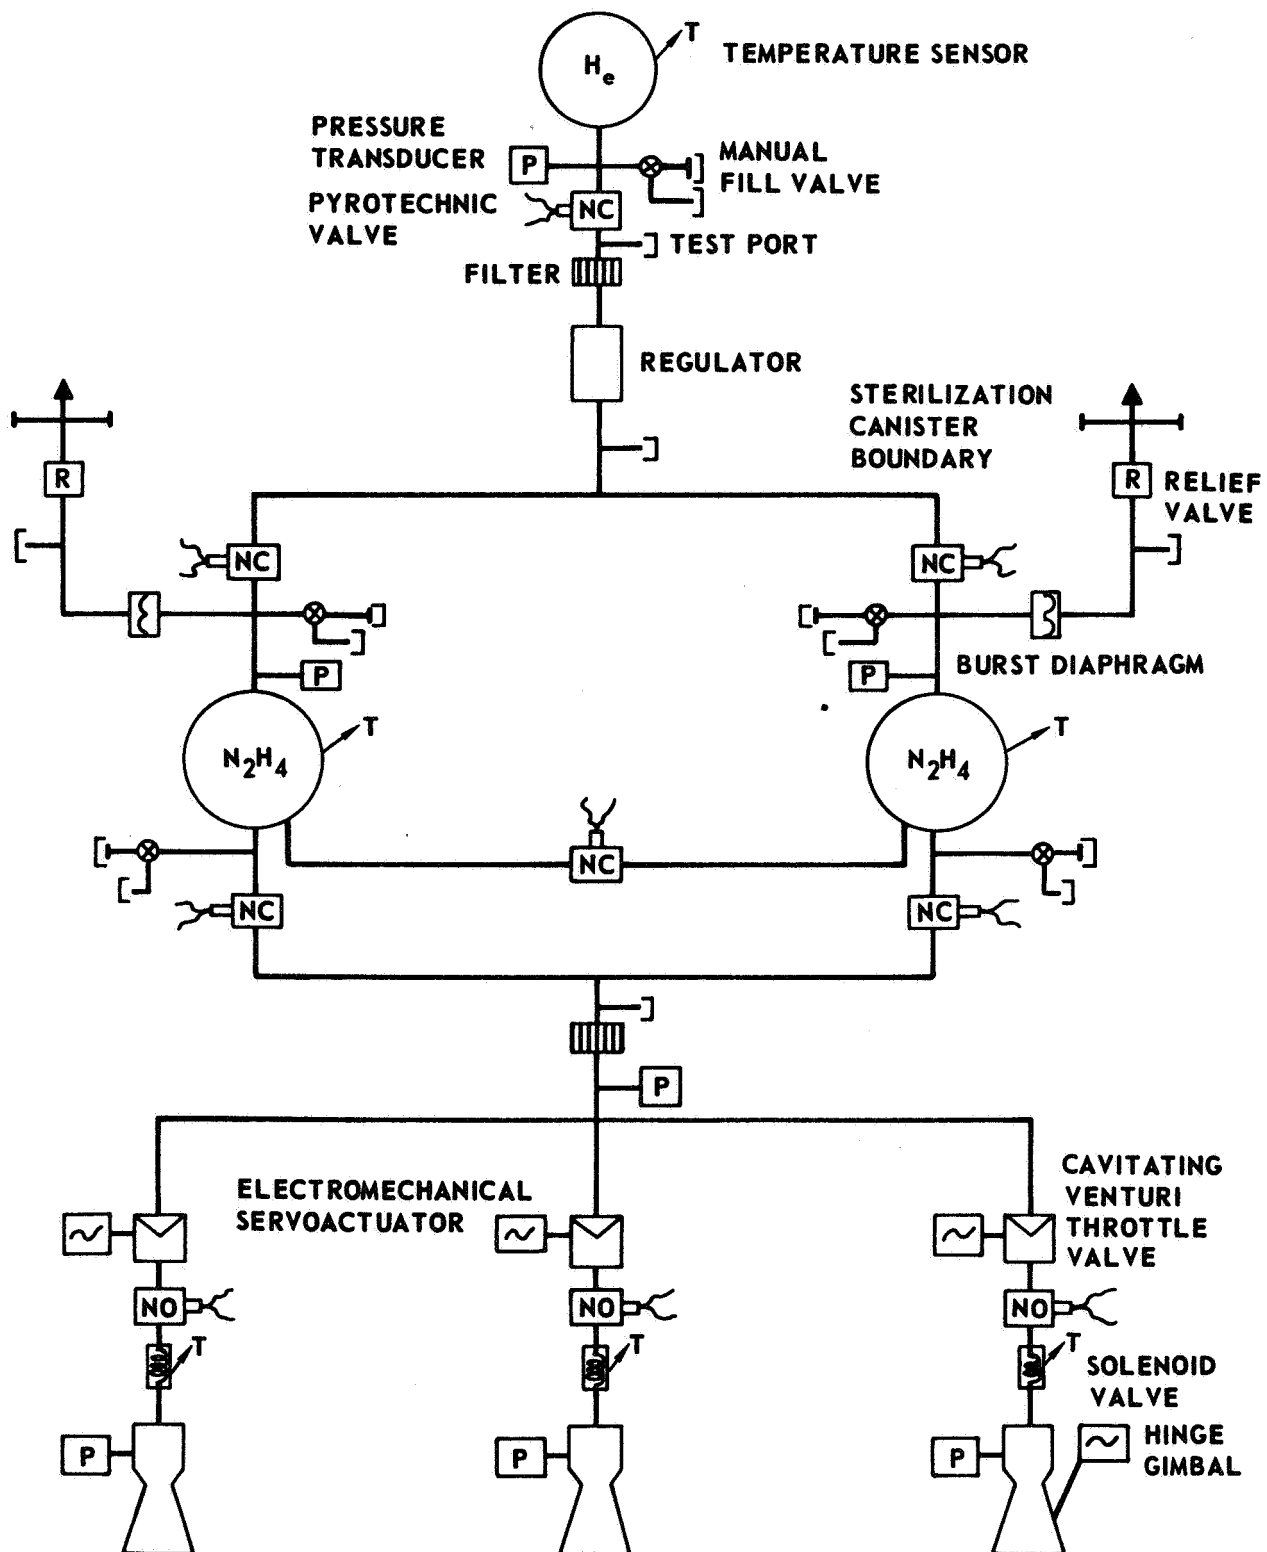

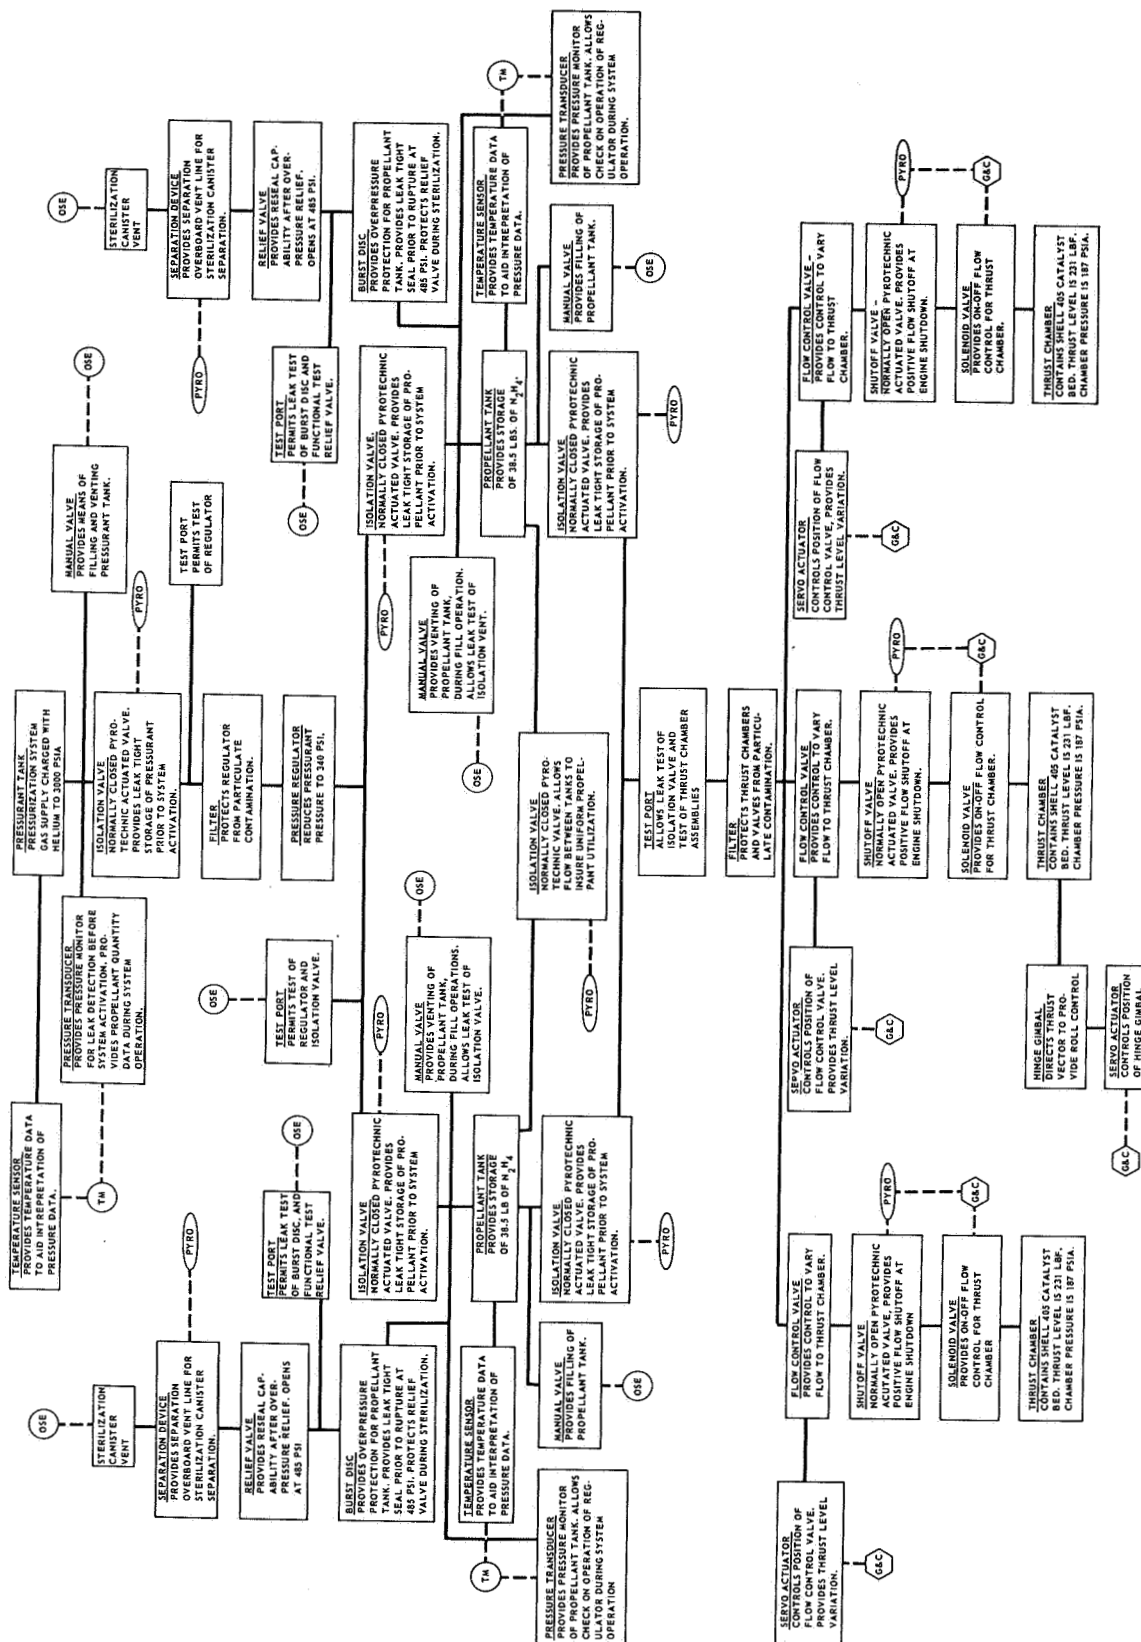

FIGURE 4.1.2.7-7

4.1.2-77

# TERMINAL PROPULSION SYSTEM FUNCTIONAL BLOCK DIAGRAM CONCEPT I

**FIGURE 4.1.2.7–8**

The hydrazine propellant is stored in two equal volume tanks. These tanks are spherical in shape and are fabricated from 6Al-4V titanium to minimize propellant decomposition. A large diameter transfer manifold between the tanks ensures equal propellant utilization during system operation. Propellant migration during the zero-g cruise and orbit portions of the mission is prevented by installation of a normally-closed pyrotechnic valve in the propellant transfer manifold. Manual access valves upstream and downstream of the tanks provide means of propellant servicing. The propellant is isolated before use by normally-closed pyrotechnic valves.

Critical components are protected from contamination by in-line filters. Test ports are installed throughout the system to facilitate system checkout.

Each of the three engines employs a cavitating venturi throttle valve, solenoid valve, and thrust chamber assembly (TCA). The cavitating venturi throttle valve serves two functions: first, it controls propellant flow rate to the engine, and second, it decouples the feed system from downstream pressure oscillations, thereby minimizing the possibility of overall system instability. The TCA employs a catalytic decomposition reaction chamber using Shell 405 spontaneous catalyst. A hinge-gimbal on one engine provides roll control.

The physical and performance characteristics of the terminal propulsion system are presented in Figure 4.1.2.7-9.

Operational Description - Operation of the TPS is initiated during the final moments of aerodeceleration (parachute or AID).

Propellant settling results from atmospheric drag-induced deceleration of the lander prior to system arming (no supplementary positive expulsion or propellant orientation devices are required). The pressurization sequence is initiated when the signal is given for deployment of the parachute or AID. At this point the isolation valve pyrotechnic circuits are armed. Following an approximate 12 second delay, the normally closed propellant tank isolation valves are fired permitting propellant to flow to the engine solenoid valves under its own vapor pressure. The pressurant system isolation valves are fired 5 seconds later to pressurize the propellant ullage. This pressurization procedure precludes large hydraulic surge pressures and entrainment of pressurant bubbles in the propellant feed lines.

**FIGURE 4.1.2.7-9**

At a prescribed range of 6500 feet, a signal from the altimeter opens the engine solenoid valves, allowing propellant flow to the TCA. The propellant decomposes upon contact with the catalyst to provide the required thrust. Electromechanical servoactuators, controlling the cavitating venturi throttle valves and engine gimbal mechanism respond to signals from the guidance electronics to vary the thrust and roll control moment for descent and attitude control.

Exhaust contamination and alteration of the surface is minimized by shutting down the engines approximately 10 feet above the surface. A backup signal is sent simultaneously to normally open valves just upstream of the solenoids to insure against propellant leakage which would interfere with post-landed operations.

Development Status - Except for the engines, the terminal propulsion system depicted in Figure 4.1.2.7-7 is within state-of-the-art technology. Additional development effort is required to meet sterilization requirements but the feasibility of heat-sterilizing liquid propellant systems has been demonstrated at JPL and Martin-Marietta. Many problems were encountered, i.e., shifts in regulated pressure, dielectric failure of solenoid valves, seal leakage, desensitized pyrotechnics and propellant decomposition. However, failure analyses, and in some cases retest, have shown that these anomalies can be circumvented by proper material selection and careful control of detail design and process procedures.

Adaptations of many existing component designs also appear feasible. For the system described herein, a Menasco tank (PN 812500-501), with modification of outlet tube stub and increased wall thickness, is suitable for pressurant storage. This tank has a minimum volume of 1275 in<sup>3</sup>.

Pressurant flow requirements can be met with an existing regulator - Fairchild Hiller Stratos-Western, PN 385000. The regulator is a series-redundant unit weighing 3.5 lbs and is employed in the Apollo Lunar Module ascent stage. Its rated flow rate is approximately 145 SCFM, helium. Seal modifications would be required to comply with sterilization requirements; the outlet pressure rating would be increased from 181 psi to 340 psi.

No gravity feed propellant tanks of the required pressure and volume presently exist. A new propellant tank development is therefore required. The tanks will be constructed of 6Al-4V titanium to minimize propellant decomposition. Decomposition rates measured during propellant-material compatibility tests at McDonnell indicate that a 3% ullage volume at 275°F is sufficient for in-tank sterilization.

The throttleable, monopropellant hydrazine engine poses the greatest risk to system development. The major cause of problems is the fact that the most suitable catalyst found to date (Shell 405) possesses very weak structural properties, due to the necessity of providing high porosity for good performance. The catalyst particles are subject to breakup during engine firing, causing an attendant loss in catalyst material and rough engine operation. This damage can occur through a number of mechanisms including: differential thermal expansion between the catalyst and engine wall, vibration, poor assembly procedures, and excessive injection velocity.

Maintaining injector and catalyst bed pressure drops within acceptable design limits over the full throttle range will be a major development task. Control of these parameters is believed to be less critical with in injector which provides catalyst bed penetration. This technique is employed on the Walter Kidde Inc. 270 lb<sub>f</sub> hydrazine engine. In this design, injector tube elements extend into the catalyst bed and propellant is distributed through radial holes in each element. The engine is scheduled to complete qualification testing for a classified program in November, 1968. Due to its development status, the Kidde engine was selected for this design. The required maximum thrust level is achieved by appropriate adjustment of propellant feed pressure.

4.1.2.8 Auxiliary aerodynamic decelerator system. - The 34.3 lb decelerator system consists of the following major elements:

- o Parachute
- o Riser Assembly
- o Reefing Line Cutters
- o Deployment Bag
- o Catapult Assembly

The relationship of the system components is shown in Figure 4.1.2.8-1 and a functional block diagram is shown in Figure 4.1.2.8-2.

Parachute - Candidate parachute types are the ringsail, cross and disk-gap-band. For a ringsail type, the nominal parachute diameter,  $D_o$ , is 30.1 feet. The canopy material will be of the 330 Nylon or Dacron type. Preliminary analysis indicates that no reefing will be required. However, until further analysis confirms this, provisions will be made for the installation of a reefing line and reefing line cutters.

Riser Assembly - The riser assembly attaches the parachute to the capsule. It is connected to the canopy at the four suspension line connector links and to the capsule at the four structural attach points. The riser is constructed from low elongation Dacron webbing.

Reefing Line Cutters - If reefing is necessary to reduce opening shock loads on the canopy, reefing line cutters with a prescribed time delay will be used to sever the parachute reefing line. The cutters are installed in pockets sewn to the canopy skirt. Line stretch at parachute deployment pulls the firing pin to initiate the pyrotechnically actuated cutters. A typical reefing cutter, which is shown in Figure 4.1.2.8-3, has an aluminum tubular body containing a spring-loaded firing pin, a time delay cartridge, and a cutter blade. A hole is provided near one end of the cutter body to insert the reefing line.

Parachute Deployment Bag - The parachute canopy, suspension lines, and a portion of the riser assembly are stowed in the parachute deployment bag

FIGURE 4.1.2.8-3

within the catapult canister. The important features of the bag are shown in Figure 4.1.2.8-4.

The deployment bag is constructed of cloth with reinforcement webbings. To insure an orderly and controlled deployment, the parachute and riser assemblies are stowed in the deployment bag in the following manner. The apex of the parachute canopy is tied with a break cord to the top inner end of the deployment bag. The canopy is folded and stowed in an accordian fashion with each folded layer being tied to restraining tabs on the interior of the bag. Four large canopy closure flaps are sewn to the inner wall of the bag and are folded down on the canopy. These flaps restrain the parachute canopy by means of a lock tab, through which the suspension line bundle is passed to form a loop lock for these flaps. This method of storage prevents the canopy from being dumped prior to the complete deployment of the suspension lines. The remainder of the suspension lines are bundled and folded in a series of loops which are stowed in a series of suspension line stowage loops sewed to the suspension line stowage flaps within the bag. The last section of the riser assembly is placed over the upper suspension line stowage flap and the bag closure flaps are sewn closed through the riser with break cord. The bag has a main riser stowage channel with two flaps which enclose and protect the riser from friction burns while the bag is leaving the catapult compartment.

Catapult Assembly - The catapult assembly is utilized to stow the parachute assembly and to provide the exit velocity required to properly deploy the parachute. The parachute deployment bag and the upper section of the riser assembly is stowed within the catapult compartment and constrained by the catapult cover. The cover is made of aluminum alloy and covered with insulation to protect the parachute from heating during descent from orbit. The cover is retained by screws located in open-ended slots. When the catapult fires, the pressure of the parachute bag against the cover causes it to "oil can" off the retaining screws, thus freeing the parachute to deploy (see Figure 4.1.2.8-5).

Nominal Performance - For the design concept, the primary aeroshell and decelerator parameters are defined in Table 4.1.2.8-1. The deployment and separation characteristics are also defined in the table for a nominal

trajectory. The parachute design was based on Mach 2, deployment for the steep, slow entry condition of the entry corridor. Deployment of the modified ringsail parachute is initiated by radar altimeter signal at 23 000 feet. Four seconds after full inflation, the aeroshell is released and allowed to fall away from the lander. The terminal descent engines are ignited on the basis of a signal from the radar altimeter at 6500 feet; immediately after ignition, the parachute is released.

Significant Requirements and Development Status - Several interrelated trade studies have identified the advantages of using a deployable aerodynamic decelerator to increase the probability of mission success. The NASA Planetary Entry Parachute Program (PEPP) has demonstrated the operational feasibility of large parachutes up to approximately Mach 2.

The catapult design illustrated in Figure 4.1.2.8-6 has been developed and fully qualified by McDonnell Douglas for the F-111 Pod Parachute Ejection System. This catapult design is capable of ejecting weights of 120 pounds at velocities of 35 ft/sec to 55 ft/sec. The design includes a crushable honeycomb feature for precise control of chamber pressure which results in uniform acceleration and velocity control. A similar system, without the honeycomb insert, was qualified to eject 120 pounds at a velocity of 100 ft/sec.

Investigations conducted on the ability of 330 Nylon parachute material to withstand the sterilization cycle have indicated that no significant degradation in material properties result from exposure to sterilization temperature (135°C) for periods of time up to 200 hours. It is believed at this time that 330 Nylon can be considered as a worthwhile candidate material.

NOTE: CATAPULT SHOWN AFTER FIRING, EXCEPT INNER BARREL RETRACTED FOR PHOTO

4.1.2.9 Aeroshell. - The aeroshell, composed of structure and heat shield, provides the velocity reduction and thermal protection to the remainder of the capsule during ballistic entry into the Martian atmosphere. The aeroshell configuration, shown in Figure 4.1.2.9-1, consists of an 8.83 ft base diameter, 60 degree half-angle sphere-cone structural shell with a spherical nose radius of 2.21 ft. The heat shield on the conical section is an ablative type foamed reinforced methyl phenyl silicone, which is hard bonded to the structure. A non-ablative material is used for heat shielding the spherical nose assembly. An instrument head is located at the apex of the nose section. A thermal curtain is attached to the aeroshell base area to provide thermal protection to the capsule.

4.1.2.9.1 Structure: The conical structure consists of a titanium single-faced, longitudinally corrugated shell with closed triangular aluminum rings. A fiberglass sandwich structure, used for the nose section, is attached to the conical shell at the cone-sphere tangency ring by a radial bolt pattern as shown in Figure 4.1.2.9-2. The total structural weight is 52.9 lb.

The conical portion consists of a forward and aft section, mechanically joined at the payload ring. Each section is composed of an 0.008 inch titanium 6AL-4V smooth outer skin, stitch welded to a 0.008 inch longitudinally corrugated inner skin. Three internal rings, including the payload ring, are mechanically joined to the inside of the corrugated inner skin. The rings are aluminum triangular torque boxes, composed of three caps and two beaded webs, with the shell providing the third web.

This configuration is designed without the need for a hoop load path in the skin. Each corrugation functions as an individual longitudinal beam to distribute loads normal to the shell surface into the triangular rings. The triangular rings provide stability for collapsing pressure and redistribute the lateral loads from unsymmetrical pressure into the overall shell.

The structural nose assembly, shown in Figure 4.1.2.9-2, is a reinforced plastic sandwich consisting of heat resistant phenolic (HRP) honeycomb core and phenolic fiberglass face sheets. It is assembled with a modified epoxy film adhesive (HT-435). The sandwich structure has a core which is 0.26 inch thick and face sheets that are each 0.020 inch thick. It is designed to be

# AEROSHELL STRUCTURAL ARRANGEMENT CONCEPT I

**CONCEPT I**

4.1.2-95

FIGURE 4.1.2.9-1

## NOSE SECTION ASSEMBLY

laid up, cured, and bonded directly to the inside surface of the prefabricated heat shield, in one assembly operation. Strength and stiffness is provided at the nose cap/conical shell joint by a channel section ring attached to a beaded circular disc with radial stiffening angles.

Fittings and brackets at the aft ring provide support for the eight reaction control jets and a truss attached to the cone-sphere tangency ring provides reaction control system equipment support.

An RF transparent window, approximately 2 by 7 inches, is provided in the conical structure for the radar altimeter.

The lander is mounted to the aeroshell by eight aluminum bipod trusses located circumferentially at equal spaces along the payload ring, as shown in Figure 4.1.2.9-1. Four bipods are attached to the lander by explosive bolts and take tension, compression, and shear loads. The other four bipods mate with the lander through preloaded sockets and take only compression and shear loads. Sixteen torsion springs near the payload ring pivot all eight bipods clear of the lander when lander/aeroshell release occurs.

4.1.2.9.2 Heat shield description - The heat protection system will protect the aeroshell structure, lander, and capsule equipment during atmospheric deceleration and entry into the Martian atmosphere. The major system components are:

- a) The spherical nose cap is covered with hardened compacted fibers (HCF) of aluminosilicate (density = 20 to 25 lb/ft<sup>3</sup>). This material is non-ablative and will not contaminate the entry science ports located in a beryllium plug at the center of the nose cap surface.
- b) The conical aeroshell surface is covered with a low density foamed silicone ablator, MDC S-20T (density = 18 to 20 lb/ft<sup>3</sup>).
- c) The HCF and S-20T are attached to the aeroshell structure with HT-424 high temperature adhesive using techniques similar to those developed for the Gemini heat shields.
- d) The aft regions of the aeroshell and lander are protected with a thermal curtain made with silica cloth.

Design Requirements and Constraints - The heat shield and curtain, after being subjected to sterilization/decontamination, ground handling, shipping, ascent, trajectory adjustment, de-orbit loads, and long-term low temperature and vacuum exposure, will provide heat protection for Mars entry.

o Non-Ablative Nose Cap - The design thickness of the nose cap limits the backface temperature to 640°F. The maximum backface temperature acceptable for structural design and bond compatibility is 735°F. Thus, the nose cap provides a thermal design margin of 95°F. The nose cap must not emit any gaseous products, during entry heating, that will compromise the mass spectrometer data on atmospheric samples.

o Ablative Heat Protection - The heat shield thickness for ablative heat protection has been sized to be compatible with the aeroshell structural temperature limits. The design heat shield thickness limits the backface temperature to 640°F. The maximum backface temperature for structural design and bond compatibility is 800°F, thus allowing a thermal design margin of 160°F.

o Thermal Curtain - The thermal curtain will enclose the base of the capsule to protect the surface lander, aeroshell structure, and equipment from

wake heating during entry, and heating during retro-rocket firing. It will help to minimize heat loss during orbital descent. The curtain must have short-term (3 minute), high temperature capability to 1500°F and be designed so that it will not interfere with separation of the lander portion of the Flight Spacecraft.

Design Entry Conditions for 1973 Flight - The entry conditions are shown in Table 4-1. Angle of attack is restricted between 0° and 30° to avoid contamination of entry science measurements.

Physical Characteristics - The heat shield consists of the non-ablative nose cap and the ablative heat protection material. The heat shield total weight is 60.0 lb. The thermal curtain weighs 11 lb.

- o Non Ablative Nose Cap - The nose cap is a spherical segment with a radius of 2.21 feet (26.5 inches) and a chord diameter of 2.21 feet (26.5 inches). The non-ablative material is a hardened compact fiber composite consisting of aluminosilicate fibers with a colloidal silica binder that is bonded to the structure with HT-424 adhesive. An instrument head imposes the use of a heat sink on the nominal stagnation point. The heat sink is a 9-1/2 inch diameter disc machined from beryllium.

- o Ablative Heat Protection - The ablative heat protection material on the conical surface is the McDonnell S-20T low density silicone ablator foamed into prebonded fiberglass honeycomb that is bonded to structure with HT-424 adhesive.

- o Thermal Curtain - The thermal curtain will be silica cloth with a black coating on both surfaces.

Operational Description - The heat shield and thermal curtain are passive devices, and as such, the Operational Description will be limited to a relation of function to mission sequence.

Following separation of the entry portion of the Flight Spacecraft and the deorbit impulse, the heat shield functions as an aerodynamic decelerator and provides thermal protection from the resulting net heat pulse. The thermal curtain protects the capsule from base heating during deorbit motor firing and wake heating during entry.

The aeroshell, including heat shield, is jettisoned after parachute deployment, while a part of the thermal curtain remains over the lander.

The thermal curtain is stripped away from the lander along with the parachute as the lander continues descent.

Performance Objectives - The heat shield will limit the backface temperature to 640°F. It shall also minimize interaction with the other capsule system, due to out-gassing prior to entry and products of decomposition during entry. The thermal curtain will isolate the aeroshell structure, surface lander, and aeroshell equipment from the effects of base heating.

Development Status - All materials selected for the entry heat protection system are available, processing procedures are defined, and fabrication methods have been developed in conjunction with selected substructures. Additional scale-up development is required for the HCF nose cap material to demonstrate that fabrication methods are satisfactory for the larger sized components. Additional tests of thermodynamic, mechanical, and entry heating characteristics shall be measured to form a complete data base for designing the heat shield.

4.1.2.10 Landing system. - The McDonnell Uni-Disc lander configuration is a large flat disc having a low landing silhouette with a low c.g. and high landing stability. This shape evolved primarily from the requirement for stable landing on extreme surface slopes and contours, and the desire to standardize the concept for varied missions. This system weighs 105.6 lb.

The lander consists of a structural base platform to which are mounted the surface payload, the terminal descent propulsion subsystem, and other Capsule support subsystems required to control descent and landing. An impact attenuation subsystem is attached to the underside of the base platform. The general arrangement is shown in Figure 4.1.2.10-1.

This configuration has been designed to the following constraints:

- a) Provide stability, strength and ample footprint to make successful landings under the following conditions:
  - o Slopes to  $20^{\circ}$
  - o Ridges with slopes  $\pm 20^{\circ}$  to horizontal
  - o Cones with slopes  $\pm 20^{\circ}$  to horizontal
  - o Surface bearing capacities of 6 psi to infinity
  - o Rocks of 5 in. diameter or smaller
  - o Vertical and horizontal velocities of 20 ft/sec and 5 ft/sec, or 16 ft/sec and 10 ft/sec, respectively.
  - o Constrain the impact felt by the surface payload to  $<25$  g.
- b) Provide a low overall c.g. of the Lander to improve stability on landing.
- c) Fit inside the 8.83 foot diameter Aeroshell.
- d) Fit sufficiently forward in the Aeroshell to maintain an aerodynamically stable c.g. for the entry vehicle.
- e) Provide a stable platform after landing.
- f) Provide good structural ties and load distributions between the aeroshell, the lander and the adapter structure.
- g) Provide an unobstructed landing radar antenna location, preferably bottom center.

# CONCEPT I LANDER GENERAL ARRANGEMENT

4.1.2-102

FIGURE 4.1.2.10-1

- h) Provide a descent propulsion engine installation with an ample moment arms, located so as not to impinge on other parts of the lander.
- i) Be compatible with clean separation from Aeroshell.
- j) Provide a simple passive system that is easily sterilized and can function after long time exposure to a hard vacuum.
- k) Use materials and techniques that are within the state of the art to minimize development risk and cost.
- l) Standardize as many systems as practical.
- m) Provide versatility and growth capabilities.

4.1.2.10.1 Physical characteristics: The landing footpad is 55.7 inches in diameter. This pad is 2.0 inches thick, with a turned-up outer lip to facilitate sliding over small obstacles. The footpad is made up of titanium radial beams, rings, and lower skin. Sufficient structural rigidity is required to uniformly distribute impact loads to the crushable attenuator when the lander lands on one edge or on peaks and ridges. The nozzles of the terminal descent engines thrust downward through three 9.0 inch diameter holes between the radial beams of the footpad.

The base platform is made up of eight titanium I-beams, 2 inches deep, with 1.3 inch caps, equally spaced in a radial spoke arrangement as shown in Figure 4.1.2.10-2. Maximum diameter is 54.7 inches.

The impact attenuator is installed between the landing footpad and the base platform. It is a crushable cylinder of aluminum honeycomb, such as "Trussgrid", 10 inches high and 38.4 inches in diameter with a 1.6 inch wall thickness. This attenuator is bonded and mechanically keyed to both the footpad and the base platform through structural channel rings, to insure the transfer of landing loads. The attenuator material has a crushing strength of 75 psi and a density of 3.3 lb/cu ft.

Eight tension cable pulley assemblies are mounted to the ends of the radial I-beams of the base platform outboard of the attenuator. These cables tie the footpad to the base platform and serve as pivot points for the rigid footpad when it lands on the opposite edge. By forcing the footpad to rotate about this point the entire crushable attenuator is put into compression, thus eliminating tension loads across the bond between the attenuator and adjoining

# LANDER STRUCTURAL ARRANGEMENT CONCEPT I

## BASE PLATFORM STRUCTURE

LANDER STRUCTURAL ARRANGEMENT (Continued)

structures. As the attenuator crushes, spring loaded cable pulley assemblies take up the cable slack and one-way ratchets prevent cable lengthening. This insures a repeat attenuation capability should the Lander bounce and land on the opposite edge. In addition, this continuous snugged-up condition of the structure and the impact attenuator insures attenuation of the horizontal velocity loads through the attenuator. (These horizontal loads may also be dissipated, in part, through friction between the footpad and the Mars surface when sliding occurs).

Secondary structures are used to support various electronic equipment as well as the terminal descent propulsion tankage.

Eight aluminum channel beams connect the ends of the eight primary radial I-beams of the base platform, forming a peripheral octagon shape. The terminal descent system tanks are supported from the radial I-beams of the base platform by tubular struts in a manner to allow for thermal variations.

The terminal descent motors are mounted to the radial I-beams of the base platform. The terminal descent propulsion system is shown in Figure 4.1.2.10-1.

4.1.2.10.2 Landing system operation: At a point 10 feet above the Mars surface the terminal descent engines are cut off allowing the lander to free fall from that height. Because of the  $\pm 5^\circ$  variation in trajectory angle and a  $\pm 5^\circ$  attitude error from uneven engine tail off, the lander may be rotated as much as  $10^\circ$  from horizontal on impact. This  $10^\circ$  tilt, when coupled with landing on a  $20^\circ$  slope, imposes an equipment installation clearance line of  $30^\circ$ , as shown in Figure 4.1.2.10-3.

In the case of a straight flat impact at zero horizontal velocity on a level surface, the footpad distributes the loads uniformly to the crushable attenuator. The attenuator absorbs sufficient energy to reduce the loads felt by the surface payload and associated equipment during landing impact to no more than 25 g. In this case the eight tension cable assemblies merely roll up the slack cable created by crushing the attenuator.

The landing radar antenna which is mounted to the bottom center of the footpad, the frangible nozzles of the terminal descent engines, and the radar altimeter antenna are crushed during landing.

For the case of an off-center landing on a slope, ridge or peak, coupled with horizontal velocity the operation is as follows:

The off-center vertical load outboard of the attenuator ring is introduced through the footpad to the attenuator. Because the footpad is a stiff structure, it would begin to rotate about the part of the attenuator nearest the impact point if not restrained by the tension cable assemblies. This rotation of the footpad would put tension loads on the bond between the attenuator and the footpad on the side opposite the impact point. This would cause footpad/attenuator separation and only local crushing of the attenuator ring. Use of the tension cables prevents this separation and forces the crushable ring to compress over its entire area.

The one-way ratcheted cable pulleys keep the footpad tight against the attenuator and keep the system operational during bouncing or sliding. The base platform provides a rigid structural backbone and reacts the loads introduced by the attenuator and the tension cables through the radial I-beams.

When the lander has come to rest, short stabilizing legs are extended to minimize disturbances during the landed operations. These legs are mounted flush with the underside of the impact footpad, so as not to be damaged on impact or during skid out. The shoe of the stabilizer is attached to a spring-loaded scissors mechanism, which is held in the stowed position by a bolt extending through a pyrotechnic bolt cutter. The three stabilizers, when simultaneously released, extend downward until meeting a 50 pound resistance, or until they are fully extended to 12 inches. A one-way ratchet mechanism locks the stabilizer at any point through its stroke, allowing it to support its full portion of the lander weight. Figure 4.1.2.10-4 shows the mechanical details of the landing system.

4.1.2.10.3 Interfaces: There are two separation interfaces on the lander. These are Aeroshell to lander, and lander to adapter.

Aeroshell to Lander - This system consists of eight separate bipod trusses which are attached and hinged to the Aeroshell at sixteen places on the second (payload attachment) ring. These bipods are spring loaded to swing outboard to provide maximum clearance for lander separation. The apexes of the bipods

UNI-DISC LANDER STABILIZING LEG (Continued)

4.1.2-110

FIGURE 4.1.2.10-4

attach to the ends of the radial I-beams of the lander structural base. Four of the bipods, space 90° apart, are tied to the lander I-beams (by explosive bolts) to carry both tension and compression loads. The remaining four bipods have "ball" ends which are seated in sockets at the ends of the base platform I-beams and allow transmittal of compression loads only. All eight bipods are capable of carrying side or shear loads in the plane of the bipod. All bipods are adjustable to make up for manufacturing tolerances and meet pre-load requirements. These bipods are shown in Figure 4.1.2.10-5. The separation provisions weigh 9.1 lb.

Lander to Adapter - On the upper surface of the ends of the eight primary radial I-beams of the lander base platform structure are eight explosive bolts that attach the lander to the adapter truss section, as shown in Figure 4.1.2.10-6. This equipment weighs 8.9 lb.

Lander Separation - After de-orbit motor firing and jettisoning, the parachute is deployed at 23,000 feet. The parachute catapult reaction loads are carried through the remaining section of the de-orbit motor mounting truss structure. Parachute harness assembly lines are attached to the lander base platform at the same four points as the de-orbit motor mounting truss. After the parachute is deployed, the Aeroshell to lander interface ties are broken by firing four pyrotechnic bolts allowing the Aeroshell and the lander to be separated by differential aerodynamic drag. At an altitude of 6500 feet, 0.5 seconds after the successful starting of the terminal descent engines, the parachute is jettisoned by activating the four explosive bolts attaching the de-orbit motor support structure to the lander. The parachute carries the de-orbit motor mounting truss and the thermal control curtain away with it.

4.1.2.10.4 Impact sensor: The impact system incorporates a mechanical sensor to signal impact. This sensor is a probe or break wire subsystem that utilizes the stroking of the attenuator or the rotation of the tension cable pulley assemblies to initiate the function. This subsystem is rugged and unsusceptible to premature operation.

## AEROSHELL TO LANDER STRUCTURAL INTERFACE

4.1.2.11 Canister and adapter. - The function of the sterilization canister is to maintain sterile conditions of the lander, capsule and associated equipment from terminal sterilization until canister separation. The function of the adapter is to join the capsule to the canister and to provide capability for transferring capsule inertia loads to the canister/adapter interface.

The canister configuration, shown in Figure 4.1.2.11-1, consists of forward and aft aluminum semi-monocoque shell structure mechanically joined at the field joint ring. The canister has a maximum diameter at the separation plane of 109.50 inches and a maximum height of 82.60 inches.

A separation device is contained between each canister section field joint ring flange. In addition, pressurization and venting (P&V) equipment is installed in the canister to prevent excessive internal canister pressure.

The adapter configuration, shown in Figure 4.1.2.11-2, consists of a welded truss assembly mechanically attached to the lander at the adapter/capsule interface.

4.1.2.11.1 Canister systems: The canister system which weighs 129.6 lb consists of structure, separation, and pressurization and venting.

Structure - The canister structure is composed of two major sections or assemblies, as shown in Figure 4.1.2.11-1. Each section consists of an 0.012 inch aluminum spherical segment shell, an 0.040 inch aluminum toroidal segment, and a field joint ring. Each field joint ring is a 7075-T6 aluminum machining. Titanium bolts are used to mechanically join the sections at the field joint ring. External aluminum rings and meridional stringers stiffen the shells and provide support for the insulation blanket covering the external surface. A fiberglass window is provided in the forward section for checkout of the capsule radar altimeter after sterilization.

The aft section mates with the adapter and the interface cone in addition to the forward canister section. Bolts through the canister wall are used to attach the adapter to fittings on the interface cone. The other end of these fittings is bolted to the orbiter. The interface cone transfers loads from the canister/adapter interface to the orbiter. Use of

## ADAPTER STRUCTURAL ARRANGEMENT

4.1.2-117

FIGURE 4.1.2.11-2

the interface cone minimizes penetration, and therefore leakage, of the canister wall. Leakage is further minimized by sealing the structural joints during assembly with RTV-560, a room temperature-curing, elastomeric sealing compound.

Separation - Canister separation is accomplished at the field joint ring by detonating a dual confined explosive separation device (CESD - the device is redundant) which is sandwiched between the field joint ring flanges, as shown in Figure 4.1.2.11-3. The major elements of the separation system include the following:

- a) CESD - This device consists of a mild detonating cord (MDC), positioned by a Teflon extrusion in a stainless steel tubing which is flattened to the shape of the groove in the field joint flange. The CESD is made up of two 180° sections, sealed at each end for each groove.
- b) Stimulus Transfer Tube - This device contains an explosive for transferring the detonation to the CESD.
- c) Electro-Explosive Device (EED)
- d) Titanium Bolts - These bolts mechanically attach the forward and aft canister.

Upon receipt of an electrical signal the EED's are detonated, followed by detonation of the stimulus transfer tubes and then the CESD. Detonation of the CESD expands the steel tube and exerts a force between the clamped flanges of the field joint ring, which causes the bolts to fail in tension and the forward section of the canister to be ejected. The titanium bolts have their head end drilled to a depth which provides the desired breaking point and breaking strength. The broken bolts are constrained by a retainer from leaving the canister forward half, and the nuts are retained by nuts plates. The canister separates at a velocity of from 1.25 to 10 fps.

Pressurization and Venting - The P&V equipment, as shown in the schematic of Figure 4.1.2.11-4, maintains the internal bio-integrity of the canister and controls internal pressure during terminal sterilization until capsule

4.1.2-119

FIGURE 4.1.2.11-3

# PRESSURIZATION & VENT SCHEMATIC

4.1.2-120

FIGURE 4.1.2.11-4

separation in Mars orbit. The major components and functions of the P&V equipment are:

- a) Vent Valves - Vent valves allow sterile gas to flow out of the canister during launch.
- b) Relief Valves - Pressure operated relief valves protect the canister structure by limiting the internal pressure to 2.25 psi.
- c) Purge and Evacuation Valves - These valves are used during decontamination and sterilization cycles on the ground. They are opened in Earth orbit and remain open to bleed off any residual pressure or outgassing.
- d) Biological Filters - These filters are placed in series with each of the above valves to prevent recontamination of the canister interior if an inflow of gas through these valves occur.
- e) Pressure Switches - Differential pressure switches provide a signal to the Operational Support Equipment (OSE) to reduce pressure on the ground and a signal after launch to close the vent valves when differential pressure falls below .50 psi.

Two each of the above major components are incorporated in the P&V system so that no single failure can have catastrophic results.

The OSE Gas Servicing Unit is connected to the purge and evacuation valves as soon as the canister is closed in preparation for terminal sterilization. It maintains internal pressure from .5 psi to 2.25 psi (limit pressure).

4.1.2.11.2 Adapter structure: The 15.2 lb adapter structure is a truss assembly consisting of 16 aluminum tubular members welded into an assembly which is attached to the capsule and canister at eight points, as shown in Figure 4.1.2.11-2. The truss-type design provides a short and stiff load path between the capsule and the canister. The adapter separates from the capsule when eight explosive bolts are detonated.

The adapter is designed to support the capsule for ground handling, launch, and cruise loads, and to allow for joining or separating the capsule and canister without access doors in the aeroshell or in the canister. This

installation problem is accomplished by designing adapter-to-canister end fittings, with fixed plate nuts on the adapter side of the joint, to permit the adapter to be attached to the capsule. This assembly can then be installed within the canister aft section. Bolts which attach the adapter to the canister are installed from outside the canister with sealing washers, to complete the installation.

4.1.3 WEIGHT SUMMARY - The mass property data for Concept I is presented in Figures 4.1.3-1 thru 4.1.3-4. The Mission History Group Weight Summary, Figure 4.1.3-1, provides a weight breakdown by system at each essential point in the mission profile. This figure has the same format as the weight summary calculated by our automated weight program. The Center of Gravity (C.G.) and Inertia Summary, Figure 4.1.3-2, provides C.G. and inertia data for the modules and the total vehicle at essential points along the mission profile. This data is also presented in the same format as it is calculated by our automated weight program. The Surface Payload Weight Summary, Figure 4.1.3-3, is a breakdown by system of the landed payload weight. The Capsule Weight Summary, Figure 4.1.3-4, presents the data from Figure 4.1.3-1 in a different format. This concept was developed for the modified environment; therefore, the parametric data of Section 3.2 was not directly applicable to this point design.
